Group A streptococcus (GAS) causes disease in every continent on Earth and is unique among human pathogens in its ability to cause a wide variety of clinical infections and post-infectious sequelae.<sup>1</sup> Further, in its coevolution with humans, *Streptococcus pyogenes* has developed a myriad of molecular strategies to neutralize or bind directly to most of the important host defense molecules produced by the human host.<sup>2</sup> Thus, in pathogenesis of both acute GAS infections and the well-known postinfectious sequelae, it is the specific host response or altered host response to this unique pathogen that accounts for the morbidity and mortality. This chapter emphasizes these host-microbe relationships to explain the unique epidemiologic and pathogenic features of *S. pyogenes* and, in the next section, *Staphylococcus aureus*.

#### AGENT

*S. pyogenes* is a gram-positive, catalase-negative coccus that divides in a single plane, thus forming chains of bacteria, particularly in liquid cultures. Lancefield<sup>3</sup> developed a classification scheme based on acid-extractable polysaccharide of streptococci and, to date, groups of streptococci from A to O have been defined by such typing. Typing of strains has been simplified through the development of commercially available rapid latex agglutination schemes. Although the bacitracin susceptibility test has proved very reliable as a presumptive marker for group A, both false negative and false positive results are problematic. GAS may be grown aerobically or anaerobically and, in general, growth is enhanced in the presence of 10% carbon dioxide.

#### EPIDEMIOLOGY

The epidemiology of GAS infections is a dynamic process geographically and temporally. The declining prevalence and severity of both rheumatic fever (RF) and scarlet fever caused by GAS throughout the 20th century in much of the Western world may have been related to improved socioeconomic

conditions, timely antibiotic treatment of streptococcal pharyngitis, and secondary prophylaxis for RF.<sup>4</sup> However, these declines are more likely due to cyclic variation in the virulence of the organism. The recent outbreaks of pharyngitis, acute RF, and the newly recognized streptococcal toxic shock syndrome (strep TSS) support this concept.

The reservoirs of *S. pyogenes* in nature are the skin and mucous membranes of humans, and nearly 5% of all people, regardless of age, carry the organism in their throats. In the recent past, RF was much more common in the United States, particularly in the northern states. Currently, RF is very uncommon in the United States but is prevalent in developing countries, many of which are in tropical environments.<sup>4</sup> Impetigo is also more common in tropical areas, though elevation above sea level is also a factor that increases the prevalence of disease.<sup>1</sup> It is likely, though unproven, that skin carriage is higher in tropical areas than temperate climates, though the inverse is true for carriage of GAS in the throat. Recently, invasive GAS infections, such as strep TSS and necrotizing fasciitis, have been described with increased frequency in North America and Europe<sup>5-15</sup> and subsequently throughout tropical areas as well. The diversity of infectious diseases caused by group A streptococcus is illustrated in Box 31-1.

#### DISEASES

GAS, perhaps more than any other pathogen, has the ability to cause diverse infections. The clinical characteristics of each of these are described in the following sections.

#### Pharyngitis and the Asymptomatic Carrier

The baseline streptococcal pharyngeal carriage rate is roughly 5%, but reaches rates of 15% to 50% in school-age children in temperate climates during epidemics of GAS pharyngitis. Transmission occurs via aerosolized droplets from the upper airway of one host to another. GAS pharyngitis is most common in children 5 to 15 years of age who live in temperate climates. The cardinal manifestations of GAS pharyngitis include sore throat, submandibular and anterior cervical adenopathy, fever of greater than 38°C, and pharyngeal erythema with exudates. Acute pharyngitis is sufficient

#### Box 31-1 Streptococcal Infections and Sequelae

- Streptococcal toxic shock syndrome

to induce antibody against M protein, SLO, Dnase, and hyaluronidase, and, if present, pyrogenic exotoxins. GAS pharyngitis may proceed to scarlet fever, bacteremia, suppurative head and neck infections, Strep TSS, carrier state, RF, or poststreptococcal glomerulonephritis. Thus, the outcomes depend on the interaction between specific streptococcal virulence factors with immunologic defense molecules of the human host.

During GAS epidemics, particularly where RF or a poststreptococcal glomerulonephritis is prevalent, treatment of asymptomatic carriers may be necessary, and programs that use monthly injection of benzathine penicillin effectively reduce the incidence of GAS pharyngitis as well as RF.

## Scarlet Fever

In recent years, outbreaks of scarlet fever in the United States and Great Britain have often been associated with strains of GAS-producing pyrogenic exotoxin C.<sup>16</sup> The cases have been notably mild and the illness has been referred to as “pharyngitis with rash.” Historically, this form was known as benign scarlet fever, though scarlet fever has not always been a mild disease: Around 1900 mortality rates of 25% were common in temperate climates on both sides of the Atlantic.

Scarlet fever has been divided into the following types: mild, moderate, toxic, and septic. Thus, benign scarlet fever may be either mild or moderate, and the fatal or malignant form may be either septic or toxic. Historically, the toxic cases invariably began with a severe sore throat, marked fever, delirium, skin rash, and painful cervical lymph nodes. In severe toxic cases, fulminating fevers of 107°F, pulse rates of 130 to 160 beats per minute, severe headache, delirium, convulsions, little if any skin rash, and death within 24 hours were the usual findings. These cases occurred before the advent of antibiotics, antipyretics, and anticonvulsants, and deaths were the result of uncontrolled seizures and hyperpyrexia. The term *septic scarlet fever* refers to the form characterized by local invasion of the soft tissues of the neck and complications such as upper airway obstruction, otitis media with perforation, profuse mucopurulent drainage from the nose, bronchopneumonia, and death. Note that necrotizing fasciitis and myositis were not previously observed in association with scarlet fever.

## Soft Tissue Infections

### Erysipelas

Erysipelas is caused exclusively by *S. pyogenes* and is characterized by the abrupt onset of fiery-red swelling of the face or extremities.<sup>17</sup> Distinctive features are well-defined margins, particularly along the nasolabial fold; a scarlet or salmon-red color; rapid progression; and intense pain. Flaccid bullae filled with clear fluid may develop during the second to third day of illness, yet extension to deeper soft tissues, bacteremia, and shock occur only rarely. Surgical débridement is rarely required and treatment with penicillin is very effective. Swelling may progress despite treatment, though fever, pain, and intense redness diminish usually within 24 to 48 hours. Desquamation of the involved skin occurs 5 to 10 days into the illness and scarring of the skin does not occur. Infants and

elderly adults are most commonly afflicted. Erysipelas has become less severe since the early 1900s even before antibiotic treatment became available.

### Streptococcal Pyoderma (Impetigo Contagiosa)

The thick, crusted skin lesions of streptococcal pyoderma frequently have a golden-brown color resembling dried serum.<sup>17</sup> Children between 2 and 5 years of age are most commonly infected. Epidemics occur throughout the year in tropical areas or during the summer months in more temperate climates and are usually associated with poor hygiene. Initially, colonization of the unbroken skin occurs either exogenously from patients with impetiginous lesions or endogenously by contamination of the skin with oropharyngeal organisms. Development of impetiginous lesions requires 10 to 14 days and is initiated by minor trauma such as an abrasion or insect bite, which facilitates intradermal inoculation. Patients with impetigo should receive penicillin, particularly when numerous sites of the skin are involved, though treatment does not prevent poststreptococcal glomerulonephritis. Topical treatment with an agent effective against gram-positive bacteria, such as bacitracin or mupirocin, is also effective. About 50% of cases of impetigo currently are caused by *S. aureus*.

### Cellulitis

GAS may invade the epidermis and subcutaneous tissues, resulting in local swelling, erythema, and pain.<sup>17</sup> The skin becomes indurated and, in contrast to erysipelas, is a pinkish color. Patients with lymphedema secondary to lymphoma, filariasis, or surgical node dissection (mastectomy, carcinoma of the prostate, etc.) are predisposed to development of GAS cellulitis, as are those with chronic venous stasis and superficial dermatophyte infection of the toes. Saphenous vein donor site cellulitis may be due to group A, C, or G streptococci. Cellulitis associated with a primary focus (e.g., an abscess or boil) is more likely caused by *S. aureus*. Aspiration of the leading-edge and punch biopsy yield a causative organism in 15% and 40% of cases, respectively. Patients respond quickly to penicillin, though in some cases where staphylococcus is of concern, nafcillin or oxacillin may be a better choice, or one may need cover for methicillin-resistant *S. aureus* (MRSA) infection (discussed later in this chapter). If bluish or violet discoloration develops or if bullae become apparent, a deeper infection such as necrotizing fasciitis or myositis should be considered (see Necrotizing Fasciitis). Particularly when such patients demonstrate systemic toxicity, a serum creatine phosphokinase level should be obtained and, if elevated, prompt surgical inspection and debridement should be performed.

### Lymphangitis

Cutaneous infection with bright red streaks ascending proximally is most commonly associated with GAS, though groups C and G have also been implicated. Prompt antibiotic treatment is mandatory because bacteremia and systemic toxicity develop rapidly once infected lymphatic fluid reaches the thoracic ducts.

## Necrotizing Fasciitis

Necrotizing fasciitis, originally called streptococcal gangrene, is a deep-seated infection of the subcutaneous tissue that results in progressive destruction of fascia and fat but may spare the skin itself.<sup>17</sup> Within the first 24 hours, swelling, heat, erythema, and tenderness develop and rapidly spread proximally and distally from the original focus. During the next 24 hours, the erythema darkens, changing from red to purple to blue, forming blisters and bullae that contain clear, yellow fluid.<sup>18</sup> The purple areas become frankly gangrenous and extensive necrosis of the subcutaneous tissue ensues. Patients become increasingly toxic and develop shock and multiorgan failure. In the past, aggressive fasciotomy and débridement and application of Dakin's solution topically achieved mortality rates as low as 20%, even before antibiotics were available. The increased severity of necrotizing fasciitis that has occurred among recent cases of Strep TSS relative to shock, multiorgan failure, and mortality could be due to the increased virulence of GAS itself.

## Myositis and Myonecrosis

Historically, streptococcal myositis has been an extremely uncommon GAS infection, and only 21 cases were documented from 1900 to 1985.<sup>19</sup> Recently, an increased prevalence of GAS myositis has been reported in the United States, Norway, and Sweden.<sup>5,6,20</sup> Translocation of GAS from an asymptomatic infection of the pharynx to the muscle site must occur hematogenously because penetrating trauma is not usually a major factor. Further, most patients have not reported symptomatic pharyngitis or tonsillitis. Severe pain at the site of infection may be the only presenting symptom; swelling and erythema may be the only signs of infection. Muscle compartmental syndromes may develop rapidly. In most cases a single muscle group is involved; however, because patients frequently have bacteremia, there may be other sites of myositis or abscess. Distinguishing streptococcal myositis from spontaneous gas gangrene caused by *C. perfringens* or *C. septicum* may be difficult, although the presence of crepitus or gas in the tissue would favor a diagnosis of clostridial infection. Myositis is easily distinguished from necrotizing fasciitis anatomically by means of surgical exploration or incisional biopsy, though clinical features of both conditions overlap and 30% to 40% of patients may have both. Though soft tissue radiography, computed tomography (CT), and magnetic resonance imaging (MRI) may be useful in localizing the site of infection, these generally show only edema or soft tissue swelling and do not distinguish myonecrosis or myositis from soft tissue damage due to blunt trauma. Increasing quantities of muscle enzymes in the serum may provide a useful clinical clue of deep infection. In published reports, the case-fatality rate of necrotizing fasciitis is between 20% and 50%, whereas that of GAS myositis is between 80% and 100%. Aggressive surgical débridement is of extreme importance because of the poor efficacy of penicillin described in human cases as well as in experimental streptococcal models of myositis (see Treatment).

## Streptococcal Toxic Shock Syndrome

In the mid-1980s, reports of invasive GAS infections associated with bacteremia, deep soft-tissue infection, shock, and

multiorgan failure began to appear in the medical literature from North America and Europe.<sup>5,20</sup> Though all ages may be affected, the greatest increases have occurred among previously healthy persons from 15 to 50 years of age. Mortality rates of 30% to 70% have been described in patients with Strep TSS, in spite of aggressive modern treatment measures. The Strep TSS is defined as any GAS infection associated with the sudden onset of shock and organ dysfunction.

## Acquisition of Group A Streptococcus and Predisposing Factors

The most common sites of infection resulting in Strep TSS are soft tissue infections (necrotizing fasciitis, myonecrosis), pneumonia, postpartum sepsis, septic joint, peritonitis, and empyema. For soft tissue infection, the portals of entry are surgical site, chickenpox, insect bites, slivers, burns, and minor abrasions. The portal of entry of streptococci could not be ascertained in 45% of cases. Many of these occurred at the exact site of minor local nonpenetrating traumas (muscle strain, ankle sprain, subcutaneous hematoma, etc.). Early on, the only symptoms may be fever and severe pain. In adults, a virus-like prodrome suggestive of influenza precedes the onset of Strep TSS by several days. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) to treat pain or suppress fever may mask the presenting symptoms or predispose the patient to more severe complications such as shock.

## Symptoms

Pain is a common initial symptom of Strep TSS, is abrupt in onset and severe, and may not be associated with tenderness or physical findings. The pain most commonly involves an extremity, but may also mimic peritonitis, pelvic inflammatory disease, acute myocardial infarction, or pericarditis.

## Physical Findings

Fever is the most common presenting sign, although on admission to the hospital 10% of patients in one report had profound hypothermia secondary to shock. Confusion may be present in over half of the patients and, in some, it progresses to coma or combativeness. In our report,<sup>5</sup> 80% of patients had tachycardia and 55% had systolic blood pressure of less than 110 mmHg on admission. Although 45% of patients had normal blood pressure (systolic pressure > 110 mm Hg) on admission, in all of these patients hypotension developed within the subsequent 4 hours. Soft tissue infection evolved to necrotizing fasciitis or myositis in 70% of patients, and in these cases surgical débridement, fasciotomy, or amputation was required. An ominous sign was the progression of soft tissue swelling to formation of vesicles and then bullae, which took on a violaceous or bluish coloration. Among patients with no soft tissue infection on admission, a variety of clinical presentations were observed; these included endophthalmitis, myositis, perihepatitis, peritonitis, myocarditis, and overwhelming sepsis. Patients who experience shock and multiorgan failure without clinical evidence of local infection have a worse prognosis because definitive diagnosis and surgical débridement may be delayed.

## Laboratory Test Results

Evidence of renal involvement was apparent at the time of admission by the presence of hemoglobinuria and elevated serum creatinine level. The serum albumin level was moderately low (3.3 g/dL) on admission and dropped further (2.3 g/dL) by 48 hours. Hypocalcemia, including ionized hypocalcemia, was detectable early in the hospital course. The serum creatine phosphokinase (CPK) level is a useful test to detect deeper soft tissue infections, such as necrotizing fasciitis or myositis.

The initial laboratory studies demonstrated only mild leukocytosis, but a dramatic left shift (43% of white blood cells were band forms, metamyelocytes, and myelocytes). The mean platelet count was normal on admission but dropped to approximately 120,000 cells/mm<sup>3</sup> within 48 hours, frequently in the absence of criteria for disseminated intravascular coagulopathy (DIC).

## Bacteriologic Cultures

GAS was isolated from blood in 60% of cases, and from deep tissue specimens in 95%.

## Clinical Course

Shock was apparent early in the course and management was complicated by profound capillary leak.<sup>5</sup> Adult respiratory distress syndrome (ARDS) occurred frequently (55%) and complicated fluid resuscitation. Renal dysfunction preceded hypotension in many patients and progressed or persisted for 48 to 72 hours despite treatment. In all patients who survived, serum creatinine levels returned to normal within 4 to 6 weeks. Overall 30% to 70% of patients have died despite aggressive treatment, including administration of intravenous fluids, colloid, pressors, and mechanical ventilation; and surgical intervention, including fasciotomy and débridement, exploratory laparotomy, intraocular aspiration, amputation, and hysterectomy.

## Characteristics of Clinical Isolates of Group A Streptococci

M protein types 1, 3, 12, and 28 of GAS have been the most common isolates from patients with shock and multi-organ failure in studies made worldwide. These same strains have also been found in increased numbers from patients with pharyngitis, erysipelas, and asymptomatic carriers. Pyrogenic exotoxin A or B, or both, have been found in isolates from the majority of patients with severe infection. Infections in Norway, Sweden, and Great Britain have been primarily due to M protein type 1 strains of GAS that produce pyrogenic exotoxin B.

## POSTINFECTIOUS SEQUELAE

### Rheumatic Fever

The prevalence of acute RF (ARF) in the Western world decreased dramatically after World War II (0.5 to 1.88 cases per 100,000 school-age children per year).<sup>21</sup> In contrast, in India and Sri Lanka the prevalence of ARF has remained 140 per 100,000 for children between 5 and 19 years of age. Socioeconomic factors seem to be important because the

highest rates in all countries have been among the impoverished in large cities. Although improved living conditions and the development of penicillin have had important roles in reducing the prevalence of ARF in the United States, the decreases had actually begun before antibiotics were available. In recent years there has been a resurgence of ARF among U.S. military recruits and in the civilian population among predominantly white middle-class children.<sup>22</sup> A particularly frightening aspect of these recent civilian cases has been the low incidence of symptomatic pharyngitis (24% to 78%). Thus, our modern primary prevention strategy (diagnosis of acute GAS pharyngitis with penicillin treatment within 10 days) would not have prevented ARF in these cases.<sup>23</sup>

Variations in the expression of virulence factors of "rheumatogenic strains" of *S. pyogenes* may best explain these fluctuations in ARF. M protein types isolated from RF patients (i.e., types 1, 3, 5, 6, 14, 18, 19, and 24)<sup>4</sup> have a common antigenic domain that is immunologically cross-reactive with human heart tissue. Understanding this molecular mimicry holds great promise for the elucidation of the immune mechanisms resulting in clinical ARF. One other marker for rheumatogenicity is the mucoid appearance of fresh pharyngeal isolates from patients with ARF. In recent times in the United States, such strains have been of type 18.

Although certain M protein types are strongly associated with ARF, such strains may cause other GAS infections as well. For example, types 1 and 3 have also been associated with poststreptococcal glomerulonephritis and Strep TSS. Further, epidemics of pharyngitis caused by type 1 are not invariably associated with epidemics of RF. That host factors determine the clinical outcome of GAS infection is suggested by the observation that persons with certain human leukocyte antigen (HLA) class II antigens are predisposed to development of ARF. Further, Stollerman<sup>21</sup> suggests that a gradual acquisition of susceptibility to ARF by schoolchildren occurs after repeated infections. This is supported by the observations of Ayoub and associates, which state that ARF is uncommon in children less than 2 years old and that antibody response to streptococcal antigens is exaggerated in children with ARF compared with those with GAS pharyngitis alone.<sup>24</sup> In addition, Zabriskie and colleagues<sup>25</sup> have shown that patients with ARF demonstrate increased expression of the B-cell alloantigen D8/17 in comparison with unaffected family members, including identical twins. That some strains of GAS can cause ARF in any person is suggested by the observation that the attack rate of ARF can vary from 388 cases per 100,000, as seen in soldiers in World War II, to 1 per 100,000 today. Such fluctuations among relatively homogeneous populations separated in time suggest changes in the relative rheumatogenicity of GAS and not unique host factors.

The clinical manifestations of ARF are multiple and, because each is not specific for ARF, several criteria must be met to establish a definitive diagnosis.<sup>4</sup> Simply put, two major manifestations or one major and two minor manifestations plus, in either case, evidence of an antecedent GAS infection are required for definitive diagnosis. The major manifestations and the frequency with which they occur during first attacks of ARF are as follows: arthritis (75%), carditis (40% to 50%), chorea (15%), and subcutaneous nodules (< 10%). The minor manifestations are fever, arthralgia, heart block, the presence of acute phase reactants in the blood (C-reactive protein,

leukocytosis, and elevated erythrocyte sedimentation rate), and prior history of ARF or rheumatic heart disease. Carditis, when present, occurs during the first 3 weeks of illness and may involve the pericardium, myocardium, and endocardium. Patients with pericarditis may have chest pain or pericardial effusion, whereas those with myocarditis may have intractable heart failure. Manifestations of acute endocarditis include the development of new murmurs of mitral regurgitation or aortic regurgitation, the latter being sometimes associated with a low-pitched apical mid-diastolic flow murmur (Carey-Coombs murmur). Murmurs of mitral stenosis and aortic stenosis are not detected acutely during first attacks of ARF but are chronic manifestations of rheumatic heart disease. Migratory arthritis involves several joints, most frequently the knees, ankles, elbows, and wrists, in more than 50% of patients.

Each involved joint has evidence of inflammation that characteristically resolves within 2 to 3 weeks with no progression to chronic arthritis or articular damage. Subcutaneous nodules occur several weeks into the course of ARF and are found over bony surfaces or tendons. They last only 1 to 2 weeks and have, in some cases, been associated with severe carditis. Erythema marginatum is an evanescent, nonpainful, erythematous eruption occurring on the trunk or proximal extremities. Individual lesions can develop and disappear within minutes, but the process may wax and wane over several weeks or months. Sydenham's chorea often occurs later in the course than other manifestations of ARF and is characterized by rapid nonpurposeful choreiform movements of the face, hands, and feet. Attacks usually disappear during sleep but may persist for 2 to 4 months.

### Poststreptococcal Glomerulonephritis

Acute glomerulonephritis (AGN) can follow either pharyngeal or skin infection and is associated with GAS strains possessing M protein types 12 and 49, respectively.<sup>1</sup> During epidemics of skin or pharyngeal infection produced by a nephritogenic strain, attack rates of 10% to 15% have been documented with latent periods of 10 days after pharyngitis and 3 weeks after pyoderma. Nonspecific symptoms include lethargy, malaise, headache, anorexia, and dull back pain. The classic signs of AGN are all related to fluid overload and are manifested initially by edema, both dependent and periorbital. Hypertension develops in most patients and is usually mild. Severe cases may be characterized by ascites, pleural effusion, encephalopathy, and pulmonary edema, though evidence of heart failure per se is lacking. Evidence of glomerular damage by renal biopsy has been documented in nearly 50% of contacts of siblings with AGN, suggesting that, as in ARF, subclinical disease is not uncommon after infection with certain strains of GAS. Unlike RF, but similar to scarlet fever, glomerulonephritis occurs most commonly in children between 2 and 6 years of age. Like ARF and scarlet fever, AGN may affect several members of the same family. Recurrences or secondary attacks occur only rarely and there is little to suggest that AGN progresses to chronic renal failure.

The differential diagnosis of poststreptococcal AGN must include Henoch-Schönlein disease, polyarteritis nodosa, idiopathic nephrotic syndrome, leptospirosis, hemolytic-uremic syndrome (*Escherichia coli* O157:H7), and malignant

hypertension. The diagnosis is simpler if there has been a recent history of symptomatic GAS pharyngitis, impetigo, or scarlet fever. Elevated or rising antibody titers to streptococcal antigens such as ASO, anti-DNase A or B, or antihyaluronidase are helpful, though ASO concentration may be low in patients with pyoderma. A careful urinalysis to document proteinuria and hematuria should be performed, but it is mandatory to demonstrate red blood cell casts because the latter is the hallmark of glomerular injury. The blood urea nitrogen and creatinine values are elevated and, if nephrotic syndrome is present, the serum cholesterol level may be elevated and serum albumin concentration low. Twenty-four-hour excretion of protein is usually less than 3 g and total hemolytic complement and C3 levels are markedly reduced. The potential role of streptococcal infections in predisposing to other syndromes such as pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS) remains unclear.<sup>26</sup>

### PATHOGENESIS AND IMMUNITY

*S. pyogenes* is a unique human pathogen because it causes multiple and distinct clinical syndromes and has developed unique ways to interact with and neutralize host defense mechanisms. Some of these virulence factors facilitate invasion, inhibit phagocytosis, and contribute to pathogenesis.

Adherence of cocci to the mucosal epithelium is a crucial step in the pathogenesis of pharyngitis and RF and it occurs via the complex interaction of fibronectin-binding protein, lipoteichoic acid, peptidoglycan, and M protein with cell surface structures including fibronectin. It is unclear if penetration of epithelial cells is important in the pathogenesis of pharyngitis but it is important in invasive diseases such as bacteremia. How GAS penetrates cells or migrates between cell junctions to reach the deeper tissue is not understood. Studies by Hanski and Caparon<sup>27</sup> suggest that carbon dioxide and oxygen may alter expression of M protein and fibronectin-binding protein. Once within the tissues, the organism evades the host's inflammatory defenses by destroying or inactivating complement-derived chemoattractants (C5a peptidase),<sup>28</sup> dysregulating endogenous complement inhibitory factors (factor H),<sup>29</sup> and binding or inactivating immunoglobulin (M protein and M protein-like proteins). Expression of M protein, in the absence of type-specific antibody, protects the GAS from phagocytosis by polymorphonuclear leukocytes (PMNs) and monocytes, and secretion of streptolysin O (SLO) in high concentration destroys approaching phagocytes. Distal to the focus of infection, lower concentrations of SLO stimulate PMN adhesion to endothelial cells, effectively preventing continued granulocyte migration.

Cytokines, in particular tumor necrosis factor (TNF), are produced by monocytes and lymphocytes in response to many different GAS factors, including peptidoglycan, SLO, and SPEB. These cytokines play important roles in the development of fever, shock, and multiorgan failure associated with Strep TSS, but are also responsible for the fever and rash associated with scarlet fever. A unique feature of the pyrogenic exotoxins and some M protein fragments is their ability to interact with certain V $\beta$  regions of the T-cell receptor in the absence of classic antigen processing by antigen-presenting cells (APCs). In the nonimmune host, SLO, SPEA, and other

streptococcal components stimulate host cells to produce TNF and interleukin-1 (IL-1). In addition, the superantigens associated with GAS induce not only IL-1 and TNF- $\alpha$  from monocytes but induce clonal proliferation of T lymphocytes with massive production of the lymphokines, interferon- $\gamma$  (INF- $\gamma$ ), IL-2, and TNF- $\beta$ . These monokines and lymphokines together then mediate hypotension and stimulate leukostasis, resulting in shock, microvascular injury, multiorgan failure, and, if excessive, death.

## Bacterial Cell Structure and Extracellular Products

### Capsule

Some strains of GAS possess luxuriant capsules of hyaluronic acid, resulting in large mucoid colonies on blood agar. In recent times this mucoid phenotype has been associated with M protein types 1, 3, and 18 strains isolated from patients during epidemics of streptococcal pharyngitis and secondary RF.<sup>4</sup>

### M Proteins

Over 150 different M types of GAS are recognized, based either on antibody recognition typing of the M protein expressed or by sequencing of the *emm* gene itself. M protein is a coiled  $\alpha$  helix consisting of four regions of repeating amino acids (A–D): A proline-glycine-rich region serves to intercalate the protein into the bacterial cell wall, and a hydrophobic region acts as a membrane anchor. Region A near the N-terminal is highly variable, and antibodies to this region confer type-specific protection, likely due to enhanced opsonization of the M protein.<sup>29</sup> Within the more conserved B–D regions lies an area that binds one of the complement regulatory proteins (factor H). The net effect is to sterically inhibit antibody binding and complement-derived opsonin deposition, thus effectively camouflaging the organism against immune surveillance. M protein also inhibits the phagocytosis of *S. pyogenes* by PMNs, though this property can be overcome by type-specific antisera. Kotb and associates have shown that fragments of M protein can also act as superantigens.<sup>30</sup> The regulation of M-protein synthesis is not firmly established but may be controlled by genetic elements of a *vir* gene composed of an upstream control sequence coupled to gene segments coding for M protein, immunoglobulin-binding proteins, and C5a peptidase.<sup>28</sup> Observations by Lancefield<sup>3</sup> suggest that the quantity of M protein produced decreases with passage on artificial media and conversely increases rapidly with passage through mice. During untreated pharyngitis, the quantity of M protein produced by an infecting strain progressively decreases during convalescence.

### Cell Wall

The cell wall, which is composed of a peptidoglycan backbone with integral lipoteichoic acid (LTA) components, provides a rigid exoskeleton containing the delicate cytoplasmic and genomic elements of the bacteria. Besides their structural functions, both peptidoglycan and LTA have important interactions with the host immune system (see later discussion).

## Hyaluronic Acid Capsule

This structure confers a mucoid appearance to colonies of GAS. Its role in pathogenesis has yet to be defined. Strains that are highly mucoid likely adhere to and invade epithelial cells less well than nonmucoid strains. However, a keratinocyte receptor (CD44) has been shown to bind to hyaluronic acid capsule. Once a barrier has been breached, the capsule may provide protection from phagocytosis and in general these mucoid strains are more virulent if injected subcutaneously.<sup>31</sup>

### Cytoplasmic Membrane

Little is known about the function and composition of the cytoplasmic membrane, though it is clear that it does serve as an effective barrier to the external milieu and also is the site of cell wall synthesis, which is in turn orchestrated by five different penicillin-binding proteins (PBPs) found within membrane fragments. The regulation of cell-wall degradation and synthesis during chain elongation is a dynamic process whose control is a reflection of the metabolic activity of the cell. Interestingly, this process becomes dysregulated in the presence of cell wall–active antibiotics. All PBPs are expressed during log-phase growth of GAS, and it is at this stage that penicillin's effects are greatest.<sup>32</sup>

### Streptolysin O

SLO belongs to a family of oxygen-labile, thiol-activated cytolytic toxins (TACs) and causes the broad zone of beta hemolysis surrounding colonies of GAS on blood agar plates. TAC toxins bind to cholesterol moieties on eukaryotic cell membranes, creating toxin-cholesterol aggregates that contribute to cell lysis via a colloid-osmotic mechanism. Exogenous cholesterol inhibits hemolysis both in vitro and in situations where serum cholesterol is high (e.g., nephrotic syndrome); thus, elevated antistreptolysin (ASO) titers occur because either cholesterol or anti-ASO antibody “neutralizes” SLO. Several TAC toxins, including SLO, have been cloned and sequenced and there exists striking homology among SLO, perfringolysin O, and pneumolysin in a 13- to 15-amino acid sequence upstream from the cysteine residue.<sup>33</sup> The significance of SLO in pathogenesis is discussed later in this chapter.

### Deoxyribonucleases A, B, C, and D

Expression of deoxyribonucleases (DNases) in vivo elicits production of anti-DNase antibody during and after infection. Antibodies to DNase A and DNase B have proved useful in the serologic diagnosis of pharyngeal and skin infections.<sup>1,17</sup> The importance of these enzymes in the pathogenesis of GAS infections has not been proved.

### Hyaluronidase

The extracellular enzyme hyaluronidase hydrolyzes the hyaluronic acid in deeper tissues and may facilitate the spread of GAS infections along fascial planes. Its clinical importance is unknown; however, a rise in antihyaluronidase titers follows GAS infections in general, especially those involving the skin.

## Pyrogenic Exotoxins A, B, C, MF, and SSA

The pyrogenic exotoxins A, B, C, MF, and SSA, also called scarlatina toxins and erythrotoxic toxins, function to induce lymphocyte blastogenesis, potentiate endotoxin-induced shock,<sup>34</sup> induce fever, suppress antibody synthesis, and act as superantigens.<sup>35,36</sup>

The gene for pyrogenic exotoxin A (*speA*) is transmitted by bacteriophage,<sup>37</sup> and stable toxin production depends on lysogenic conversion in a manner analogous to that for diphtheria toxin production by *Corynebacterium diphtheriae*. Factors that control SPEA production are not yet understood, though the quantity of SPEA produced can vary dramatically from decade to decade.<sup>38</sup> Historically, SPEA-producing strains have been associated with severe cases of scarlet fever and, more recently, with Strep TSS.<sup>5</sup>

Although all strains of GAS are endowed with genes for SPEB (*speB*), as with SPEA, the quantity of toxin produced varies greatly. SPEB is related to the proteinase precursor and the role of each in pathogenesis has only recently been investigated.<sup>39,40</sup>

Pyrogenic exotoxin C (SPEC), like SPEA, is bacteriophage-mediated and its expression is likewise highly variable. Hallas<sup>16</sup> demonstrated that mild cases of scarlet fever in England have been associated with strains of GAS-producing SPEC.

Streptococcal superantigen (SSA) has recently been described in an M protein type 3 GAS strain isolated from a patient with Strep TSS.<sup>41</sup> This toxin has similar characteristics to those of other pyrogenic toxins and also functions as a superantigen. Its distribution among strains of GAS and its role in pathogenesis has not been defined.

Mitogenic factor (MF) has all the features of other pyrogenic exotoxins and is a potent inducer of cytokines and lymphokines and has been found in most strains of GAS examined.<sup>42,43</sup>

Many other superantigens have been described from GAS, though the role that they play in pathogenesis remains to be determined.<sup>44</sup>

## Protein F

Protein F is a fibronectin-binding protein, which, in conjunction with peptidoglycan, lipoteichoic acid and M protein, plays an important role in adherence of GAS to epithelial surfaces.<sup>44</sup> Production of protein F is inversely related to carbon dioxide concentrations in the milieu.<sup>27</sup>

## C5A Peptidase

C5A peptidase, an enzyme produced by most strains of GAS and some strains of group B streptococcus, cleaves the complement activation factor C5A and may thus impede the migration of phagocytes to the site of infection.<sup>28</sup>

## TREATMENT

### Emergence of Erythromycin Resistance

The first erythromycin-resistant strain of *S. pyogenes* (GAS) was isolated in Great Britain in 1959 and, by 1975, resistant strains had also been isolated in the United States, Canada, and Japan. Although the prevalence of erythromycin resistance among GAS strains has remained low (3.6% to 4.0%) in most

western countries, in Japan resistance increased from 8.5% to 72% between 1971 and 1974. Similarly, erythromycin resistance had been a rare finding in Sweden; however, in 1984, an epidemic of pharyngitis (294 cases) caused by erythromycin-resistant GAS was reported. Marked increases in erythromycin resistance have also been documented in Finland, Australia, and Spain, and recently, Pittsburgh.

### Sulfonamide Resistance

Sulfonamide resistance currently is reported in fewer than 1% of GAS isolates.

### Therapeutic Failure of Penicillin

The major problem in the treatment of GAS infections with penicillin is a lack of in vivo efficacy, despite in vitro susceptibility to penicillin. Penicillin failure in pharyngitis, tonsillitis, or mixed infections has been attributed to inactivation of penicillin in situ by  $\beta$ -lactamases produced by co-colonizing organisms such as *Bacteroides fragilis* or *S. aureus*. For example, this factor contributes to the 10% to 25% bacteriologic failure rate of penicillin treatment of GAS pharyngitis. Further, active selection of such  $\beta$ -lactamase-producing organisms following treatment with penicillin is well documented and leads to bacteriologic failure in 40% to 80% of patients. In support of the role of  $\beta$ -lactamase in bacteriologic failures, Smith and Kaplan described cure rates of 90% in such failures if the second treatment consisted of amoxicillin plus clavulanate compared with only a 29% cure with a second regimen of penicillin.<sup>45</sup> In addition, antibiotics that are unaffected by  $\beta$ -lactamase activity (e.g., amoxicillin with clavulanate, erythromycin, or clindamycin) have a greater efficacy than penicillin in patients with recurrent GAS tonsillitis. In penicillin-allergic patients with acute GAS pharyngitis, erythromycin, cephalosporins, and clindamycin are reasonable alternatives, and all have had greater bacteriologic efficacy than penicillin in clinical trials.

Genotypic penicillin tolerance could also explain penicillin's lack of efficacy in tonsillitis or pharyngitis. Tolerant strains demonstrate a slower rate of growth, a slower rate of bacterial killing by penicillin, and an absence of  $\beta$ -lactam-induced cell lysis. Penicillin-tolerant GAS strains have been isolated from 11 of 18 cases of penicillin treatment failures of acute tonsillitis compared with 0 of 15 from successfully treated patients. Penicillin-tolerant strains have also caused epidemics of pharyngitis.

Recently, reports that describe penicillin's reduced efficacy in the treatment of severe streptococcal infections in humans (i.e., streptococcal bacteremia, pneumonia, myositis, and Strep TSS) have surfaced. Studies in animals demonstrated that penicillin was effective if given early or if small numbers of GAS were used to initiate infection. With larger inocula, or if treatment was delayed, penicillin was no more effective than placebo. Thus, penicillin's efficacy declined as the infection became more severe. In comparative trials in animal models of GAS myonecrosis and necrotizing fasciitis, clindamycin had excellent efficacy even if treatment was delayed up to 16 hours. Recently it was demonstrated that GAS organisms in log-phase cultures produce five PBPs, whereas in the stationary phase they do not.<sup>32</sup> Thus, in fulminant infections, GAS organisms have

reached a stationary phase of growth and subsequent treatment with penicillin fails due to an absence of its high-affinity targets, the PBPs. Clindamycin's greater efficacy could be due to its ability to suppress virulence factor production (M protein and pyrogenic exotoxin), its longer postantibiotic effect, its indifference to in vivo inoculum or stage of growth, and its ability to attenuate TNF synthesis by human monocytes.

## ■ *Staphylococcus aureus* Infections

In tropical climates, the most common *S. aureus* infection is pyomyositis, though impetigo, cellulitis, carbuncles, and furuncles are also very common. In cities where intravenous drug abuse is prevalent, endocarditis and bacteremia have also been described. *Staphylococcus epidermidis* is also an important cause of intravascular, central nervous system shunt, and prosthetic joint infections. Similarly, *Staphylococcus saprophyticus* and *Staphylococcus intermedius* cause urinary tract infection and infected dog bites, respectively, in western cultures and likely cause similar problems in tropical countries as well.

### AGENT

Staphylococci are gram-positive cocci that divide in two planes, thus yielding the classic clusters of cocci. *S. aureus* colonies cause beta hemolysis on sheep blood agar plates and appear as large moist colonies that may develop a golden hue with prolonged growth or when incubated at room temperature for a few hours.

### EPIDEMIOLOGY

The normal reservoir of *S. aureus* and *S. epidermidis* is human skin. In addition, the nasal passage may harbor *S. aureus* and may provide an inoculum for those with recurrent furunculosis. *S. aureus* causes infection in healthy persons as well as compromised patients and is distributed among all peoples of the world. Clinical settings with specific staphylococcal infections are listed in Box 31-2.

#### Box 31-2 Staphylococcal Infections

Bacteremia  
Cavernous sinus thrombosis  
Cellulitis  
Endocarditis  
Furunculosis  
Impetigo  
Myositis  
Necrotizing fasciitis  
Osteomyelitis  
Pneumonia  
Septic arthritis  
Staphylococcal scalded skin syndrome  
Staphylococcal toxic shock syndrome  
Suppurative thrombophlebitis  
Surgical incision site infection

## DISEASES

### Folliculitis, Carbuncles, and Abscesses

Abscesses can develop from skin organisms introduced into the deeper tissue, from seeding of the skin from hematogenous sources such as bacteremia associated with endocarditis, or contiguously from infectious foci in the lung or gastrointestinal tract. In the former case, hair follicles serve as a portal of entry for a number of bacterial species, though *S. aureus* is the most common cause of localized folliculitis. Recurrent folliculitis is most common in black males in association with shaving (folliculitis barbae). Folliculitis can progress to small subcutaneous abscesses (furuncles), which either resolve with antibiotic treatment alone or progress to form very large, exquisitely painful carbuncles that require surgical drainage as well as antibiotics. Certain individuals seem predisposed to develop recurrent *S. aureus* infections (recurrent furunculosis) and most have underlying factors such as poor hygiene, nasal carriage of staphylococcus, or neurodermatitis. Though it is suggested that diabetic patients are prone to such infections, there are few data to support this concept. In contrast, patients with Job's syndrome classically have recurrent *S. aureus* infections. In addition, these patients have eosinophilia and high levels of immunoglobulin E (IgE) antibody in serum.

Treatment of recurrent furunculosis may require surgical incision and drainage as well as antistaphylococcal antibiotics such as nafcillin parenterally or dicloxacillin orally. Prevention is difficult, but some success has been realized with intranasal bacitracin or mupirocin ointment and hexachlorophene (pHisoHex) baths (in adults). Prophylactic antibiotics should be used only in severe cases.

Sebaceous glands empty into hair follicles and the ducts, if blocked (sebaceous cyst), may resemble a staphylococcal abscess or may become secondarily infected. Chronic folliculitis is uncommon except in acne vulgaris where normal flora, for example, *Propionibacterium acnes*, may play a role. Hidradenitis suppurativa occurs in either acute or chronic forms and can lead to recurrent axillary or pudendal abscesses.

### Impetigo

Impetigo contagiosa is caused by *S. pyogenes*, and bullous impetigo by *S. aureus*. Both skin lesions may have an early bullous stage but then appear as thick crusts with a golden-brown color. Streptococcal lesions are most common in children 2 to 5 years of age, and epidemics may occur in settings of poor hygiene and particularly in children from lower socioeconomic conditions in tropical climates. It is important to recognize impetigo because of its potential relationship to poststreptococcal glomerulonephritis.

### Pyomyositis

Pyomyositis is usually due to *S. aureus*, is common in tropical areas but rare in temperate climates, and commonly there is no known portal of entry. The most common presenting features are muscle pain (100%) and fever (81%).<sup>46</sup> Blood cultures are positive in 14.3% of cases and common complications are bronchopneumonia (23.1%) and empyema (19.2%) and mortality is low (7.7%). In one series there was an association with tuberculosis of the dorsal-lumbar spine.<sup>46</sup> Infection remains

localized and shock does not occur, unless strains produce toxic shock syndrome toxin-1 (TSST-1) or certain enterotoxins. In contrast, *S. pyogenes* may induce a primary myositis referred to as streptococcal necrotizing myositis, which is associated with severe systemic toxicity. Such infections have been described recently as part of the Strep TSS.

### Empyema

*S. aureus* is the most common cause of empyema in the pediatric age group in tropical areas and has the highest prevalence in the hottest most humid months.<sup>47</sup> Predisposing conditions were prior pustular skin lesions, measles, chicken-pox, and blunt trauma to the chest. Only 4% of strains have been methicillin-resistant *S. aureus* (MRSA), but this could increase dramatically in the future. Chest tube drainage was effective in 78% of cases; however, the remaining patients required decortication.<sup>47</sup>

### Endocarditis

*S. aureus* is an important cause of acute endocarditis worldwide. Intravenous drug abuse is the most common risk factor and in 50% of cases involves the right side of the heart. Still, fulminant staphylococcal bacteremia with endocarditis can occur in patients with no risk factors. The major complications regardless of cause are acute destruction of the aortic valve with sudden-onset pulmonary edema. In such cases, it may be necessary to replace the aortic valve immediately to prevent the development of left ventricular dilatation and subsequent myocardopathy. Patients with right-sided endocarditis are less prone to cardiovascular collapse but may develop multiple staphylococcal abscesses of the lung. Regardless of the location of the vegetations, some patients develop metastatic abscesses of the liver, spleen, bones, and kidney. (See also later discussion of MRSA.)

## Staphylococcal Toxic Shock Syndrome

### Epidemiology

Toxic shock syndrome associated with *S. aureus* infections was originally referred to as TSS,<sup>48</sup> though in this chapter this syndrome is designated Staph TSS to distinguish it from Strep TSS. Between 77% and 93% of cases of Staph TSS have occurred in females and the vast majority (> 90%) of these women were white and 15 to 19 years of age.<sup>49–54</sup> The incidence of Staph TSS was highest in 1980 and ranged from 2.4 to 16 per 100,000 population.<sup>52,53,55–58</sup> Because most of these studies were performed using similar techniques and case definitions, the differences in incidence of disease likely represented bona fide epidemiologic variations—with northern California having the lowest<sup>58</sup> and Colorado<sup>57</sup> having the highest infection rates. Following the peak of reported cases of Staph TSS in 1980, a marked and persistent decline ensued. Numerous epidemiologic studies established that the illness was associated with females during their menstrual cycles and that *S. aureus* colonization and infection within the vagina played a significant role.<sup>49–57</sup> The toxin, TSST-1, was isolated from *S. aureus*<sup>59,60</sup> and found to be produced by over 90% of *S. aureus* strains isolated from menstrual cases of Staph TSS.<sup>61</sup>

The marked decline in the incidence of Staph TSS that began in 1981 has many possible explanations. First, there may have been enhanced reporting of cases in 1980 owing to extensive media coverage. Second, this decline could be related to education of the patients at risk, loss of virulence of the microbe, or acquisition of immunity to the putative toxins by a significant segment of the population. Lastly, some suggest that the reduced prevalence was due to removal of Rely tampons. Clearly, the last does not explain this epidemiologic phenomenon fully because menstrual cases of Staph TSS continue to occur. For further discussions about the epidemiologic studies implicating tampons, and Rely in particular, the reader is referred to the literature.<sup>49–52,62,63</sup>

Also in the early 1980s it was established that nonmenstrual cases of Staph TSS occurred among both sexes, regardless of age, and were associated with surgical procedures such as rhinoplasty with Teflon stents or nasal packing.<sup>64</sup> Nonmenstrual cases have also been described in association with a variety of primary *S. aureus* infections, including cutaneous infection, postsurgical or postpartum infection, focal tissue infection, and pneumonia with or without antecedent influenza infection.<sup>65</sup> In contrast to menstrual cases of Staph TSS, TSST-1 has been detected in only half of strains isolated from patients with nonmenstrual Staph TSS.<sup>61,64</sup> Finally, staphylococcal enterotoxin B (SEB) and, to a lesser extent, enterotoxins A (SEA) and C (SEC) have been found in the remaining strains.<sup>66–69</sup> In addition, case reports suggest that strains that produce TSST-1 together with SEC may be more likely to cause fatalities,<sup>67,68</sup> but luckily both toxins are rarely found together in the same strain.<sup>69</sup>

### Clinical Presentation

A prodromal period of 2 to 3 days precedes the physical manifestations of Staph TSS and consists of malaise, myalgia, and chills.<sup>70</sup> Fever begins soon thereafter, followed by symptoms of lightheadedness, modest confusion, and lethargy. The majority of patients develop diarrhea early in the course. Symptoms of hypovolemia, due in part to capillary leak and diarrhea, then predominate and include hyperventilation, palpitations, and dizziness on standing. Confusion, a prominent feature of Staph TSS, may affect some patients' ability to recognize the seriousness of their illness, resulting in delayed treatment.

When patients are first examined, fever, tachycardia, tachypnea, and hypotension are usually present. A transient, erythematous rash has been observed in over 50% of patients and may be either diffuse or patchy in distribution.<sup>70</sup> Many patients have marked peripheral vasodilation associated with high cardiac output and thus erythematous skin may represent maximal capillary dilation due to toxins or endogenous mediators. The capillary leak mentioned previously may not be apparent until fluid resuscitation has been undertaken. Desquamation of skin, particularly at sites of a previous erythematous rash, occurs between 7 and 14 days.<sup>70</sup>

### Pathogenesis and Immunity

There is little doubt that TSST-1 and staphylococcal enterotoxins are the major virulence factors associated with cases of Staph TSS. There is substantial evidence that the genetic determinants for TSST-1 and SEB are neither plasmid- nor bacteriophage-mediated and that the gene is a variably expressed,

mobile element, likely a transposon.<sup>71</sup> There has been intense research to elucidate the environmental and genetic control mechanisms responsible for enhanced toxin production. Clearly, neutral pH, iron, trace elements such as magnesium and calcium, as well as oxygen enhance TSST-1 production.<sup>63</sup> Toxin is produced mainly during the late log phase and early stationary phases of growth.

Extrapolation of these findings to the apparent increased risk of menstrual Staph TSS with tampon use in 1980 has been more difficult if not controversial. Some suggest that tampons could (1) increase vaginal partial oxygen pressure, at least during placement, thereby stimulating toxin synthesis by colonizing strains of *S. aureus*, (2) supply surfactants that could increase toxin production, and (3) bind magnesium and shift the growth kinetics of staphylococci toward enhanced toxin production.<sup>65</sup> Thus, modest quantities of these toxins, locally produced, interact with the immune system, first at the site of infection and then systemically.

Monocytes, as well as a mononuclear cell line, have the ability to bind TSST-1 and staphylococcal enterotoxins. In addition, these toxins bind to specific sites on the  $V_{\beta}J\beta$  region of the T-lymphocyte receptor (TCR). Simultaneous binding to both monocyte and T lymphocyte results in T-cell proliferation (blastogenesis) and activation of both cell types via the superantigen mechanism.<sup>72</sup> Recent studies have shown that activation of the T cell via this mechanism requires the appropriate toxin, viable T lymphocytes bearing a specific V repertoire, and either a viable APC, a nonviable APC, or a fragment of the major histocompatibility complex (MHC) class II receptor.<sup>73</sup> Other accessory molecules may also participate in the docking between MHC class II and TCR. One of the T-lymphocyte binding sites for enterotoxin appears to be CD4.<sup>74</sup> CD4 site binding could serve to stabilize the complex between the TCR and MHC class II. Further, blocking of other surface molecules such as ICAM-1, CD11a, CD28, or CD2 with monoclonal antibodies effectively prevented T-cell proliferation in the presence of SEB.<sup>75</sup>

The consequences of superantigen stimulation of the immune system are T-lymphocyte proliferation and generation of vast quantities of the lymphokines IL-2, INF- $\gamma$ , and TNF- $\beta$ <sup>72,76,77</sup> as well as the monokines TNF- $\alpha$ , IL-1, and IL-6,<sup>35,76</sup> yet the dynamics of production are quite different for each. Specifically, during the first 24 hours, production of TNF by peripheral blood mononuclear cells (PBMCs) predominates. By 48 hours, TNF- $\beta$  is detectable, and at 72 hours, equal quantities of TNF- $\alpha$  and TNF- $\beta$  can be measured.<sup>76</sup>

The control mechanism of cytokine production via the superantigen mechanism is poorly understood, but both counterregulatory cytokines and accelerated programmed cell death are likely involved. For example, the conventional wisdom regarding T-cell proliferation describes the initial proliferation of T cells in response to superantigens followed by the rapid depletion of T-cell subsets bearing the specific V repertoire through accelerated programmed cell death or apoptosis.<sup>67</sup> T-lymphocyte dynamics have been studied in a mouse model of SEB-induced shock.<sup>78,79</sup> There was clear evidence of V-selective clonal expansion 24 to 48 hours after administration of SEB.<sup>78,79</sup> On day 3, clonally expanding cells became depleted through accelerated programmed cell death (apoptosis) resulting in anergy.<sup>78,79</sup> McCormack and colleagues<sup>80</sup> demonstrated that this expansion-deletion sequence occurs predictably in vivo

when high concentrations of a superantigen are used. However, deletions also occur using low dosages. In fact, concentrations that were insufficient to cause T-cell blastogenesis in vivo were still capable of depleting specific V subsets of T lymphocytes.<sup>80</sup> Using sublethal concentrations of a superantigen, Miethke and coworkers<sup>81</sup> demonstrated that 4 to 6 hours after in vivo challenge with SEB, BALB/c mice became resistant to an otherwise lethal dose of SEB plus D-galactosamine.<sup>81</sup> These authors demonstrated that PBMCs harvested from such animals during this time lost the ability to release lymphokines such as TNF- $\beta$  and IL-2.<sup>81</sup> They hypothesized that endogenous corticosteroids released in response to the first wave of lymphokines induced by SEB may have suppressed T-cell responsiveness. Though this might be an adequate explanation, counterregulatory cytokines likely play a more important role. For example, 10 ng/mL of IL-10, a regulatory cytokine produced by the Th2 subset of CD4+ helper T lymphocytes, inhibited synthesis of TNF- $\beta$  and INF- $\gamma$  production by TSST-1-stimulated PBMCs by 68% and 86%, respectively.<sup>82</sup> The relevance of this endogenous control mechanism in vivo is uncertain since only 72 pg/mL of IL-10 was produced in vitro by PBMCs stimulated with TSST-1,<sup>82</sup> a concentration well below that used in the in vitro studies. Krakauer<sup>82</sup> points out that exogenous administration of recombinant IL-10 might be a rational treatment for superantigen-induced disease. Recent studies showing that IL-10 protected animals from lethal challenge support this hypothesis<sup>83</sup> (see also discussion under Treatment). Interestingly, IL-10 did not inhibit T-lymphocyte blastogenesis,<sup>82</sup> suggesting that IL-10 works largely by inhibiting transcriptional events.

Though the previously described animal models of superantigen injection demonstrate lethality, what is the evidence that *S. aureus* toxins such as TSST-1 or the enterotoxins cause an illness resembling Staph TSS? The animal model that has been best studied in this regard is the rabbit whiffle ball model. Briefly, sterile plastic chambers are implanted beneath the skin of rabbits and allowed to mature over the course of 3 to 4 weeks. Strains of *S. aureus* are then inoculated into these chambers and physiologic measurements of blood chemistries, blood pressure, pulse, temperature, and mortality are recorded. Scott and coworkers<sup>84</sup> and Rasheed and colleagues,<sup>85</sup> using this model, and De Azevedo and associates,<sup>86</sup> using an implanted uterine diffusion chamber model, demonstrated that strains producing TSST-1 were more likely to induce a toxic shock-like syndrome than strains that did not produce TSST-1. Strains of *S. aureus* that produced altered TSST-1 toxins lacking the ability to induce mitogenicity were nontoxic in the rabbit whiffle ball chamber model,<sup>87</sup> though the reason for the loss of mitogenicity was unexplained. Subsequently, using both genetically altered SEC mutants and peptide fragments of SEC to stimulate lymphocyte proliferation in vitro, it was determined that toxin binding to the  $\alpha$  helix of the MHC class II portion of the APC was critically important in the induction of lymphocyte blastogenesis.<sup>88</sup>

The role of TSST-1 in inducing a TSS-like illness is also supported by the demonstration that a neutralizing monoclonal antibody prevented illness in rabbits challenged with a TSST-1-producing strain of *S. aureus*.<sup>89</sup> Parsonnet and colleagues<sup>90</sup> have also developed a slow infusion model that allows the investigation of purified, recombinant, and genetically altered toxins.

## Treatment and Prognosis

Patients diagnosed as having Staph TSS will be profoundly hypotensive, tachycardic, and febrile, and may have evidence of coagulopathy. The general supportive measures described in the previous section apply to Staph TSS as well. Clearly, in menstrual cases, early removal of the tampon and irrigation of the vaginal vault are important. Similarly, in non-menstrual cases, surgical débridement, drainage, and removal of stents and packing are vital.<sup>91</sup>

Antibiotic treatment based on in vitro susceptibility would suggest that nafcillin, first- or second-generation cephalosporins, vancomycin, clindamycin, erythromycin, and fluoroquinolones would be reasonable choices. A variety of these antibiotics have been used in the last 15 years, and the mortality rate for Staph TSS remains at about 3% for menstrual cases and is two- to threefold higher for nonmenstrual cases.<sup>63</sup>

As with Strep TSS, shock and organ failure in patients with Staph TSS is clearly the consequence of the deleterious effects of extracellular proteinaceous toxins on the immune system. Thus, antibiotics that suppress protein (toxin) synthesis might be more efficacious than cell wall-active antibiotics, as has been described in the previous section. Clindamycin in concentrations that are either above the minimal inhibitory concentration (MIC)<sup>92</sup> or below it<sup>93</sup> suppress TSST-1 synthesis by strains of *S. aureus*. Parsonnet and coworkers<sup>94</sup> demonstrated that clindamycin, erythromycin, rifampin, and fluoroquinolones all suppressed TSST-1 synthesis by greater than 90%. In contrast, five different  $\beta$ -lactam antibiotics, including nafcillin and cephalosporins, increased measurable TSST-1 in culture supernatants, probably by releasing intracellular stores of toxin in part by causing direct lysis or by increasing the permeability of the cell wall.<sup>94</sup> Unfortunately, there has been no controlled clinical trial comparing different antibiotics; however, these results suggest that antibiotic susceptibility alone may not necessarily predict success.

The potential use of immunoglobulin to treat Staph TSS has a sound basis (see also the section on Strep TSS Treatment). First, many investigators have demonstrated that patients who develop Staph TSS have low to absent antibody titers against TSST-1 or enterotoxins or both.<sup>63</sup> Second, the general population in both the United States and Europe has significant antibody titers against these toxins and titers increase with age.<sup>63</sup> This latter finding is supported by the observation that pooled immunoglobulin preparations have high titer antibody against TSST-1.<sup>63</sup> Finally, there are recent data in experimental animals that antibody which neutralizes TSST-1 is therapeutic.<sup>95,96</sup> There have been no prospective studies done in humans.

The usefulness of corticosteroids in shock has been studied for many years. Corticosteroid therapy is not currently considered to be an effective treatment in the United States, though some centers in Europe currently use this treatment. Todd<sup>91</sup> advocates corticosteroids for patients with "severe Staph TSS unresponsive to initial antibiotic therapy."

## TREATMENT

### Cellulitis

Because of the diverse causes of cellulitis, empirical choices of antibiotic therapy depend greatly on the clinical

factors described previously. Once cultures and sensitivities are available, choices are much easier and more specific. The physician must first decide if the patient's illness is severe enough to require parenteral treatment either in the hospital or on an outpatient basis. For presumed streptococcal or staphylococcal cellulitis, nafcillin, cephalothin, cefuroxime, vancomycin, or erythromycin are good choices. Cefazolin and ceftriaxone have less activity against *S. aureus* than cephalothin, though clinical trials have shown a high degree of efficacy. Ceftriaxone may be a useful choice for outpatient treatment because of once-per-day dosing. Similarly, teicoplanin, like vancomycin, has excellent activity against *S. pyogenes* and both *S. aureus* and *S. epidermidis* and may be given once per day by intravenous or intramuscular injection. For patients being treated with oral drugs, dicloxacillin, cefuroxime axetil, cefpodoxime, or erythromycin (or clarithromycin or azithromycin) are effective treatments. For known group A, B, C, or G streptococcal infections, penicillin or erythromycin should be used orally or parenterally. In serious group A streptococcal infections, clindamycin is superior to penicillin. This is probably because in this type of infection, wherein large numbers of bacteria are present, streptococci are in a stationary phase of growth and do not express a full complement of PBPs. In contrast, clindamycin is not affected by inoculum size or stage of growth. In addition, clindamycin suppresses production of extracellular toxins by both *S. aureus* and *S. pyogenes*.

### Methicillin-Resistant *S. aureus* Infections

During the last 15 years, there has been a slow but steady increase in the prevalence of MRSA in all communities of the world, including Indonesia, Japan, India, North and South America, and Europe. Until 2002, these strains were all associated with hospital-associated (HA) MRSA infections and the greatest risk factors were prior hospitalization, surgical procedures, and recent antibiotic exposure, particularly fluoroquinolones,  $\beta$ -lactam antibiotics, and vancomycin. Currently, a dramatic increase in community-associated (CA) MRSA infections has been reported. These are most commonly associated with soft tissue infections, though pneumonia, toxic shock syndrome, and necrotizing soft tissue infections have been described.<sup>97,98</sup> Vancomycin has been the drug of choice, though it is slowly bactericidal and does not penetrate tissues, particularly the lung, very well. Linezolid has been shown to be an effective agent for skin and soft-tissue infections, bacteremia, and pneumonia caused by MRSA. Recently, daptomycin, which is rapidly bactericidal, has also been approved for MRSA skin and skin structure infections. Clinical trials are under way for an indication in MRSA endocarditis, though it is not yet approved for this purpose. Unfortunately, HA MRSA strains are also resistant to many other antibiotics. CA MRSA strains are less likely to be resistant to trimethoprim-sulfamethoxazole and tetracyclines, but inducible clindamycin resistance has emerged as a potential problem in 20% to 30% of strains. These dynamic changes in the susceptibility of *S. aureus* cause great difficulty in recommending specific treatments for both HA and CA MRSA. The clinician must factor in the prevalence of MRSA in his or her environment and the seriousness of the infection in selecting empiric antibiotics. It is more important than ever to obtain cultures and rely on sensitivities to guide subsequent treatment.

## PREVENTION AND CONTROL

Prevention and control of streptococcal and staphylococcal infections and their sequelae are best accomplished by careful personal hygiene and prompt treatment of early infections. Extensive regimens to eradicate carriage may have a role in selected cases of recurring infections.

# Pertussis

EMILY J. WONG  
ERIK L. HEWLETT

## INTRODUCTION

Pertussis, or whooping cough, remains a significant cause of morbidity and mortality worldwide. Despite the availability of vaccines effective in preventing infection by *Bordetella pertussis*, an estimated 50 million cases occur each year, resulting in 300,000 deaths. The majority of these cases occur in developing countries, where malnutrition and limited supportive care contribute to the case fatality rate in infants, which can reach 4%.<sup>1,2</sup> Even in countries where pertussis vaccination is widely available, there is still a significant burden of pertussis disease, particularly in adolescents and adults.<sup>3-9</sup>

## AGENT

Pertussis is caused by coccobacillary organisms from the genus *Bordetella*. *B. pertussis* and *B. parapertussis* are responsible for whooping cough illness in humans; there are additional *Bordetella* species, including *B. bronchiseptica*, *B. avium*, *B. hinzii*, *B. holmesii*, and *B. trematum*.<sup>10-14</sup> Although *B. bronchiseptica* is primarily an animal pathogen, it can cause respiratory illness in humans, often via transmission from animals.<sup>15,16</sup>

Both *B. pertussis* and *B. parapertussis* have been isolated from patients with clinical pertussis, and there are cases in which dual infection has been documented.<sup>17</sup> However, *B. parapertussis* does not produce pertussis toxin, one of the major virulence factors of *B. pertussis* contributing to severity of disease,<sup>18,19</sup> and infection with *B. parapertussis* is rare in infants less than 6 months old. Therefore, *B. pertussis* is believed to be the predominant cause of severe pertussis disease and mortality and is the focus of the World Health Organization (WHO) pertussis surveillance.<sup>2</sup>

## EPIDEMIOLOGY

Pertussis has a worldwide distribution, but the lack of active surveillance in many countries has resulted in a paucity of reliable data from some regions of the world, particularly Africa. Historically, pertussis has persisted in communities as an endemic disease with 3- to 5-year periodic cycles of epidemics. Recent outbreaks have occurred in settings associated with crowded living conditions (e.g., military units, the Hajj pilgrimage, oil refinery workers)<sup>20-22</sup> and communities with low vaccination rates (e.g., Afghanistan).<sup>23</sup>

Reported incidences of disease in unimmunized populations are as high as 6000 per 100,000 child-years <15 years

of age and 18,000 per 100,000 child-years <5 years of age.<sup>2,24</sup> Following pertussis vaccine introduction, incidence drops to <20 per 100,000 person-years,<sup>2,9,25</sup> but can rise to rates of 300 to 500 cases per 100,000 person-years owing to disease in adolescents and adults.<sup>4,7,26</sup>

Prior to the introduction of whole-cell pertussis vaccine, many infants had passive immunity from maternally transmitted antibodies. Pertussis was primarily an illness of young children (aged 2 to 10 years), who thereby acquired natural immunity that was subsequently boosted through repetitive exposures in the community. As a result of widespread use of pertussis vaccine, there has been a shift in the age distribution of pertussis cases. Infants are born unprotected owing to the lack of maternal pertussis antibodies. Following immunization, young children acquire immunity that wanes as they approach adolescence. This susceptible older population is now capable of transmitting pertussis to each other and to the next generation of infants. In a number of countries, an initial decrease in pertussis disease was followed by a rise in incidence years later, with a higher proportion of cases occurring in adolescents, adults, and infants, and a lower proportion occurring in young children.<sup>5,6,8,9</sup> Although pertussis immunization remains effective, its duration of protection is limited, resulting in a growing number of susceptible older individuals and infants without passively acquired antibodies.

## DISEASE

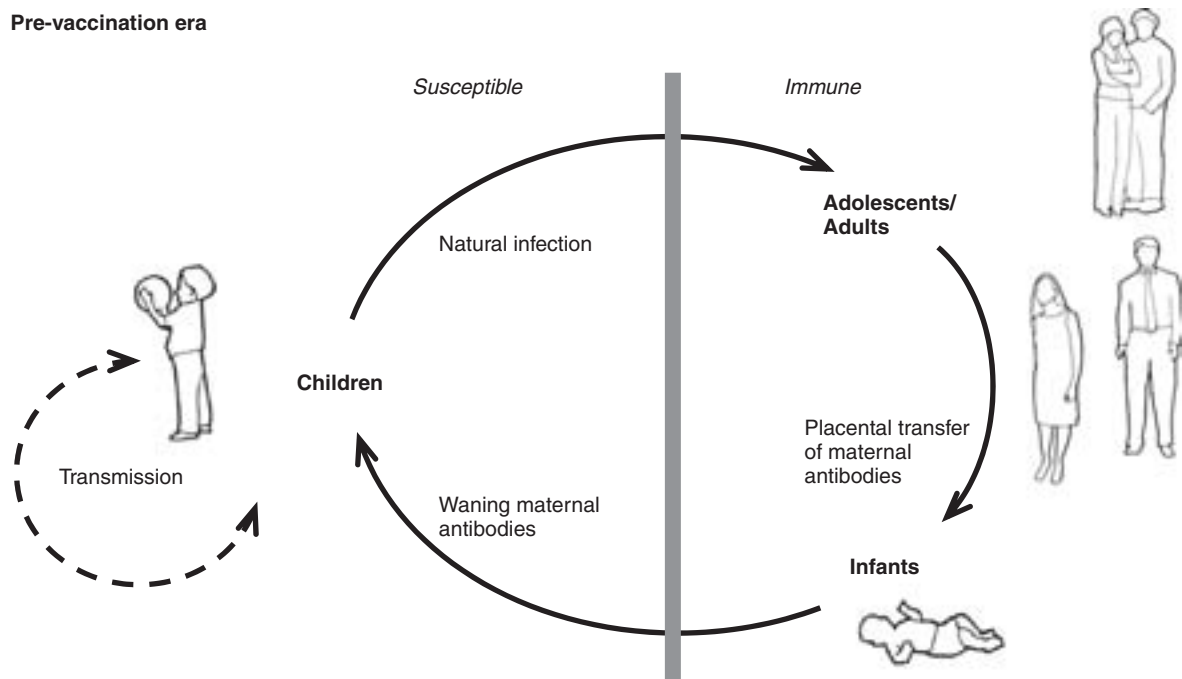

Pertussis infection is acquired by the transmission of *B. pertussis* via aerosol droplet during close exposure to a person with active infection. An asymptomatic incubation period ranging from 1 to 3 weeks is followed by the catarrhal phase, with symptoms including rhinorrhea, watery eyes, dry cough, mild conjunctival injection, malaise, and low-grade fever.<sup>27</sup> This phase can be clinically indistinguishable from many other upper respiratory tract infections and lasts approximately 1 week. As the illness progresses to the paroxysmal phase, infected individuals may develop the characteristic paroxysmal cough—a series of short expiratory bursts—followed by an inspiratory gasp that produces the typical whoop. Paroxysms and whoop are relatively uncommon in infants, who may have episodes of apnea as the sole manifestation of disease. Associated with the paroxysmal cough are the symptoms of post-tussive emesis, cyanosis, facial flushing, and syncope.<sup>3,28,29</sup> Patients, especially those who are unimmunized, may exhibit leukocytosis with lymphocyte predominance.

During the paroxysmal phase, which can last for weeks to months, there can be significant morbidity and mortality, especially in developing countries where malnutrition and dehydration lead to greater severity of disease.<sup>30</sup> The principal complications include pneumonia (caused by *B. pertussis* or other pathogens), conjunctival hemorrhages, ulceration of the lingual frenulum, rectal prolapse, and central nervous system (CNS) dysfunction. CNS abnormalities can present as encephalopathy or seizures and are seen more frequently in infants and young children.<sup>8,31</sup>

Following the paroxysmal phase, the convalescent phase is a time when paroxysms decrease in frequency and intensity. The duration of this phase can be several months, and exposure to other respiratory pathogens or even simple stimuli such as cold air, can precipitate recurrence of the paroxysmal cough.

*Bordetella pertussis*: Transmission and immunity

**Pre-vaccination era**

**Post-vaccination era**

## **PATHOGENESIS**

*B. pertussis* produces a number of virulence factors that interact in an orchestrated sequence of events required for development of the clinical disease of pertussis. Despite knowledge of the mechanisms of action of several of these factors at the cellular and molecular level, their exact target tissues and pathophysiology remain a matter of speculation. A current working model for the pathogenesis of pertussis involves adhesins, toxins, and other virulence factors.<sup>32–34</sup> The adherence factors—filamentous hemagglutinin (FHA), pertactin (PRN), and fimbriae (FIM)—appear to be involved in the attachment of *B. pertussis* to ciliated respiratory epithelia, but no single factor is absolutely essential to establishment of infection. The release of tracheal cytotoxin (TCT), a breakdown product of the bacterial peptidoglycan, causes ciliostasis and death of the tracheal ciliated epithelial cells. Adenylate cyclase toxin (ACT) produces an accumulation of cyclic adenosine monophosphate (cAMP) intracellularly, which impairs the function of leukocytes and may affect other cell types. Other pathogenic factors produced by *B. pertussis* (dermonecrotic toxin, tracheal colonization factor, and an autotransporter/serum resistance factor, BrkA) have also been described.

The best-known product of *B. pertussis* is pertussis toxin (PT),<sup>35</sup> which induces lymphocytosis, enhances insulin secretion, inhibits intracellular signal transduction, and impairs the function of phagocytes. As the only component that seems to disseminate systemically, PT appears to be the main contributor to the more severe manifestations of disease and the resulting sequelae. However, the target tissues of PT that are responsible for specific symptoms remain to be elucidated.<sup>36</sup>

## **DIAGNOSIS**

Historically, the diagnosis of pertussis infection has been limited by a lack of a sensitive and specific diagnostic method that is also practical for widespread use. Isolation of the *B. pertussis* organism by culture by use of Bordet-Gengou agar or newer media is very specific but has low sensitivity, even in experienced laboratories. Epidemiologic studies and vaccine efficacy trials have used serology to diagnose pertussis infection by detecting antibodies against pertussis or pertussis components in the serum. However, there is not yet a fully standardized methodology for pertussis serology, and published studies have used a variety of serologic case definitions.<sup>4,5,29,37</sup> Serology has limited clinical utility when an acute diagnosis is needed, especially if paired acute and convalescent sera are required for diagnosis.

Polymerase chain reaction (PCR) assays for *B. pertussis* are highly sensitive and specific and are increasingly available for routine diagnosis in clinical settings.<sup>3,38</sup> Because PCR does not require a viable organism, the diagnosis of pertussis infection can sometimes be made in patients who have already received treatment with antibiotics or who present for care later in the course of illness.<sup>39</sup> Recent advancements in PCR allow discrimination between *B. pertussis* and *B. parapertussis*.<sup>40–42</sup> Despite its advantages, PCR cannot identify phenotypic variations among pertussis strains or potential antibiotic resistance that can be detected using culture isolates; it is also more costly and is less widely available in developing countries.

Diagnosis of a clinical case of pertussis can be made on the basis of clinical presentation when specimens are not available or in areas where laboratory diagnosis is not possible. WHO recommends that a clinical case of pertussis be diagnosed by a physician or be defined as a cough lasting at least 2 weeks with at least one of the following symptoms: paroxysms of coughing, inspiratory whooping, or post-tussive vomiting without other apparent cause. A case that meets the clinical case definition and is supported by a laboratory test is considered a laboratory-confirmed case.<sup>2</sup>

## **TREATMENT**

Supportive therapy is critical for infants with pertussis disease, who are at the greatest risk for complications and neurologic sequelae. They often require hospitalization for close monitoring, frequent nasotracheal suctioning, supplemental oxygen, and parenteral hydration and nutrition. There has been little advancement in specific antimicrobial therapy for pertussis in the past 25 years. Although some antibiotics have been shown to eliminate *B. pertussis* from the respiratory tract, thereby reducing transmission of the organism, their efficacy in reducing the severity and duration of disease appears dependent on early initiation of therapy. Erythromycin (particularly the estolate ester) is recommended at a dose of 40 to 50 mg/kg/d (maximum 2g/d) divided into 4 doses, for a full 14-day course to prevent bacteriologic relapse.<sup>43–46</sup> The newer macrolides—clarithromycin and azithromycin—have good in vitro activity against pertussis and supportive clinical experience. Although there are no standard doses for pertussis, studies suggest clarithromycin 7.5 mg/kg (maximum 500 mg) twice a day for 7 days, or azithromycin 10 mg/kg/d (maximum 500 mg) on day 1 then 5 mg/kg/d (maximum 250 mg) for 4 subsequent days.<sup>47–49</sup> When a macrolide is not available or cannot be tolerated, trimethoprim-sulfamethoxazole can be used, but there are few published reports of its use in pertussis treatment.<sup>50–52</sup> Adjunctive therapy with corticosteroids<sup>53</sup> or  $\beta_2$ -adrenergic agonists<sup>54,55</sup> may be of some symptomatic benefit in severely affected individuals, but their efficacies are uncertain and require further study.

## **PREVENTION**

In the prevaccine era, immunity to pertussis infection was acquired and maintained through clinical disease followed by repetitive exposure to *B. pertussis* as it circulated in the community. It was soon recognized that acquisition of antibodies to the organism correlated with resistance to infection.<sup>56</sup> In the 1950s, a killed, whole-cell pertussis vaccine, combined with diphtheria and tetanus toxoids and aluminum-containing adjuvants (DTwP vaccine), was developed and widely used throughout the world. This vaccine has been shown in trials to have an efficacy of greater than 80% if properly prepared. Unfortunately, there has been significant variability in the vaccine product made by different manufacturers, resulting in lower efficacy with some products.<sup>57</sup>

In some countries, the use of the whole-cell vaccine has been limited by its associated reactogenicity, including pain, swelling, fever, anorexia, and vomiting.<sup>58,59</sup> In younger children and infants, there were reports of encephalopathy and neurologic sequelae temporally associated with DTwP but no conclusive evidence that DTwP causes CNS damage.<sup>58,60</sup>

Because of the concern over the safety of DTwP, several acellular pertussis (aP) vaccines were developed using PT and one or more of the following components: PRN, FHA, or FIM.<sup>61</sup> These vaccines have similar efficacy and decreased reactogenicity compared with whole-cell vaccines. Currently they are licensed and available in combination with diphtheria and tetanus toxoids (DTaP) in most developed countries. However, the complexity of producing purified vaccine components entails a production cost that is unreasonable for most developing countries.

WHO continues to recommend use of whole-cell pertussis vaccine in developing countries because of its lower cost of production and its greater availability, especially in countries that manufacture their own vaccine. In countries where the reactogenicity of the whole-cell vaccine is an issue and may cause decreased acceptance of pertussis immunization, WHO recommends use of the acellular vaccine.<sup>62</sup>

The duration of protection from whole-cell vaccines is 10 to 12 years<sup>3</sup> but is yet to be determined for aP vaccines. It has been observed that some *B. pertussis* strains isolated from previously vaccinated individuals have genetic variations in the components, suggesting possible postvaccinal adaptation of the organism.<sup>2</sup> Although the relevance of these observations to vaccine efficacy is not established, it is clear that the immunity induced by vaccines received in childhood wanes with time. Countries that instituted routine pertussis immunization in the 1950s observed a drop in pertussis incidence and then a resurgence in cases with a greater proportion in adolescents and adults.<sup>2–7,9</sup> Countries with recent pertussis programs are reporting similar changes. For example, following the initiation of infant pertussis immunization in Senegal, there was a decline in incidence in every age group and up to 79% reduction in children 6 to 23 months old. During an 8-year period, the median age of individuals experiencing pertussis rose from 4.1 to 6.2 years of age, and cases in children less than 5 years old dropped from 60% to 38% percent.<sup>63</sup>

Clinical trials of the newer aP vaccines have been conducted in adolescents and adults, demonstrating safety and immunogenicity.<sup>3,64,65</sup> In the one adult efficacy trial in the United States, the aP vaccine appeared to provide protection against infection, but there were too few cases to demonstrate efficacy definitively.<sup>26</sup> Acellular pertussis vaccines are now licensed and available for use in older individuals in Europe, Canada, and Australia. New recommendations to vaccinate adolescents have been made in Germany, France, and Canada; the vaccination of health-care and child care workers is recommended in the European Union and required in Germany.<sup>3,9,66</sup> It is anticipated that the U.S. Centers for Disease Control (CDC) will make recommendations for the immunization of health-care and child care workers against pertussis if the aP vaccine is approved for use in adults.<sup>67,68</sup>

WHO has not yet issued recommendations for the immunization of adults against pertussis. As childhood vaccination programs are implemented in developing countries, the age distribution of pertussis is shifting toward older individuals. A greater proportion of infants will be born to mothers with waning immunity and exposed to adults with greatest risk for infection. However, in these countries, the acellular pertussis vaccines may be unavailable or prohibitive because of cost, an important consideration in the development of future recommendations for adult immunization.

# Legionellosis

THOMAS J. MARRIE  
PAUL HOFFMAN

## INTRODUCTION

From July 21 to 24, 1976, the 58th Annual Convention of the American Legion was held at a hotel in Philadelphia. One hundred eighty-two of the attendees at the convention developed pneumonia.<sup>1</sup> One hundred forty-seven (81%) were hospitalized and 29 (16%) died. This outbreak of pneumonia, of apparent unknown cause, triggered an exhaustive epidemiologic and microbiologic investigation by the Centers for Disease Control and Prevention (CDC) culminating in the isolation of a new microorganism, *Legionella pneumophila*, approximately 6 months later.<sup>2</sup>

It soon became apparent from analysis of stored serum samples that this organism had caused disease prior to 1976, and prospective studies showed that the spectrum of illness ranged from a nonpneumonic, mild, self-limited febrile illness (Pontiac fever)<sup>3</sup> to a pneumonic illness that varied from mild to severe. The latter was often accompanied by multisystem disease.<sup>1,4</sup> The pneumonic form of the illness following infection with *Legionella* is referred to as Legionnaires' disease.

## AGENT

There are more than 30 species in the family Legionellaceae.<sup>5</sup> *Legionella pneumophila* serogroup 1 accounts for most of the cases of Legionnaires' disease. Legionellaceae are gram-negative, aerobic, non-spore-forming bacilli that measure 0.3 to 0.9  $\mu\text{m}$  wide by 2 to 20  $\mu\text{m}$  long. These organisms require special media for growth. Charcoal yeast extract agar buffered to pH 6.9 and containing  $\alpha$ -ketoglutarate along with cefamandole, polymyxin B, and anisomycin to prevent growth of other microorganisms is the primary medium used for isolation of these organisms. Addition of  $\alpha$ -ketoglutaric acid to the medium promotes growth of *Legionella* likely by stimulation of oxygen-scavenging enzymes.

These organisms are visualized poorly, if at all, by Gram stain. In tissue, silver impregnation stains such as the Dieterle or Warthin–Starry method allow visualization of the organism.

## EPIDEMIOLOGY

Once the microorganism had been isolated, it was characterized and diagnostic reagents became available. In 1981, 5 years after the initial outbreak, England and colleagues<sup>6</sup> reported on the first 1000 cases of sporadic Legionnaires' disease in the United States. The authors noted that most cases occurred during June to October—71% of patients were

male, and 88% were white. During the 2 weeks before onset of this illness, 37% had traveled overnight, 29% had visited a hospital, and 5% had been hospitalized 2 days before onset of illness. Twenty-three percent lived within sight of a construction or excavation site, and 32% had been exposed to a construction or excavation.

As we have learned more about the epidemiology of this disease, these were all seminal observations. With these original observations in mind, it is instructive to examine the report of Marston and associates,<sup>7</sup> which analyzed *Legionella* surveillance data on 3254 patients reported to the CDC from 1980 through 1989. Disease rates did not vary by year but were higher in the northern states and during the summer. The mean age of patients with Legionnaires' disease was 52.7 years compared with 34.7 years for the U.S. population. In contrast to earlier reports, people with Legionnaires' disease were now more likely to be black. They were also more likely to be smokers and have diabetes, cancer, acquired immunodeficiency syndrome (AIDS), or end-stage renal disease. Indeed, the observed number of cases among patients with AIDS was 42-fold higher than expected. Risk factors for mortality in the study of Marston and coworkers were older age, male sex, nosocomial acquisition of disease, immunosuppression, end-stage renal disease, and cancer. Twenty-three percent of the cases were nosocomially acquired.

Soon after the description of Legionnaires' disease, it was evident that cases could occur sporadically or in clusters. Furthermore, these cases could be community or nosocomially acquired. As with most infectious diseases, outbreaks provided an opportunity to learn about the mechanisms of transmission of Legionnaires' disease. In most instances, *Legionella* is transmitted to humans by inhalation of aerosols containing the bacteria. Outbreaks have been associated with exposure to a variety of aerosol-producing devices, including showers,<sup>8,9</sup> a grocery store mist machine,<sup>10</sup> cooling towers,<sup>11–16</sup> whirlpool spas,<sup>17,18</sup> decorative fountains, and evaporative condensers.<sup>19,20</sup> It is also likely that aspiration of contaminated potable water by immunosuppressed patients is a mechanism whereby *Legionella* is acquired.<sup>21,22</sup>

Legionellae thrive in natural and complex water distribution systems. In Nova Scotia, 6 of 7 Halifax hospitals studied had *Legionella* spp. in the potable water supply, whereas only 3 of 32 other hospitals in Nova Scotia had this microorganism in the potable water.<sup>23</sup> *Legionella pneumophila* multiplies in potable water that contains amebae but not in filtered amebae-free water.<sup>24</sup> Amebae are natural hosts for legionellae.<sup>25</sup>

Legionellosis is believed to occur worldwide, but data are limited or nonexistent for many countries. It is likely that legionellosis is very uncommon in areas without water heaters and complex water distribution systems. However, even in these areas, aspiration of contaminated natural water, such as following boating accidents, can result in Legionnaires' disease. Legionnaires' disease has been found throughout North America, Europe, the United Kingdom, Argentina and Brazil in South America, Singapore, Thailand, and Australia. A few cases of Legionnaires' disease have been reported in India. The major problem is that serologic tests and culture for legionellae are not available in most tropical countries. Indeed, Harris and Beeching<sup>26</sup> state that the Western approach to the management of pneumonia "with hospitalization and administration of antibiotics to cover typical and 'atypical'

Human cases of *Legionella pneumophila* infection

■ Known distribution

[e.g., *Legionella*] organisms is not appropriate for much of the tropics.” However, in areas where studies have been carried out, *Legionella* and Legionnaires’ disease have been found. This situation is exemplified by data from Singapore. There were 144 cases of Legionnaires’ disease from 1991 to 1995, and there was widespread contamination of water (33% of 2774 cooling towers and 18.8% of 16 outdoor fountains) by *Legionella* in that country.<sup>27</sup>

## DISEASE

Legionellosis consists of two diseases: Pontiac fever and Legionnaires’ disease. The former is a self-limited febrile illness. The incubation period is 24 to 48 hours. There is a 90% or greater attack rate among those exposed, and recovery occurs in approximately 1 week. Malaise, myalgia, fever, chills, headache, and nonproductive cough are common symptoms. There is no pneumonia.<sup>28</sup>

Legionnaires’ disease is a pneumonic illness with a wide spectrum of severity and frequency of extrapulmonary manifestations. The following is a typical case history for this disease:

A 32-year-old man, a nonsmoker and nondrinker, was admitted in July 1979 with a 1-week history of chills, rigors, and sweats, followed by anorexia, nausea, vomiting, and diarrhea. Subsequently, he developed a nonproductive cough with progressive dyspnea, wheezing, right pleuritic chest pain, and headache. His temperature was 39.5°C with evidence of pneumonic changes in the right upper lobe. The leukocyte count was  $17.2 \times 10^9/L$ , and the serum sodium was 123 mEq/L. Despite penicillin and later tetracycline therapy, there was progressive respiratory distress with spread of the pneumonic infiltrate over a 4-day period to involve the entire right lung and the left lingula. On the sixth hospital

day, further progression of the pneumonia resulted in respiratory failure, and assisted ventilation was required. Erythromycin gluceptate (500 mg intravenously every 6 hours) was started with reduction in temperature after 8 days and improvement in the pneumonic process allowing extubation. A normochromic normocytic anemia and elevated liver enzymes developed. He was discharged after 22 days in the hospital. Antibody titers against *L. pneumophila* were 1:64 (acute) and 1:64,000 (convalescent).

**Table 33-1** Comparison of Selected Features of Nosocomial Legionnaires’ Disease from Three Reports\*

Feature	Korvick and Yu <sup>29</sup>	Kirby et al. <sup>4</sup>	Marrie et al. <sup>30</sup>
No. studied	65	20	55
Male:female ratio	62:3	14:6	33:22
Mean age (yrs)	59.2	52.3	58.6
No. died	16 (24.6)	14 (70)	35 (63.3)
Immunosuppressed	27 (41.5)	18 (90)	40 (73)
Malignancy	19 (29)	7 (35)	16 (29)
Assisted ventilation	NS	NS	33 (60)
Cough	60 (92)	14 (70)	37 (67)
Chills	50 (77)	6 (30)	37 (67)
Diarrhea	30 (47)	3 (15)	12 (22)
Dyspnea	23 (36)	7 (35)	35 (64)
Chest pain	21 (33)	11 (55)	8 (15)
Hemoptysis	22 (34)	6 (30)	1 (2)
<i>Legionella</i> isolated	5 (8)	NS	40 (70)

NS, not stated.

\*Numbers in parentheses refer to percentage.

Initially, patients with Legionnaires' disease have a non-productive cough, but later in the course of the illness it can be productive. Occasionally, hemoptysis occurs and the clinical picture may mimic pulmonary embolus.

Rales and signs of consolidation are evident on examination. There may be relative bradycardia. Some patients have watery diarrhea and headache; confusion and lethargy dominate the clinical picture in others. The pneumonia may continue to progress despite appropriate treatment, and respiratory failure may ensue. In severe Legionnaires' disease, clinical improvement is not seen for 4 or 5 days after appropriate antibiotic therapy has been instituted.

Disseminated intravascular coagulation, thrombocytopenia, rhabdomyolysis, glomerulonephritis, pyelonephritis,

pericarditis, and pancreatitis may complicate the clinical course. Hyponatremia and hypophosphatemia are common.

Table 33-1 summarizes selected features of nosocomial Legionnaires' disease as reported from three different institutions.<sup>29,30</sup>

The radiographic manifestations of Legionnaires' disease consist of alveolar opacities that may be segmental or lobar and unilateral or bilateral. Pleural effusions occur. Progression of the opacities is common (Fig. 33-1). Indeed, in severe Legionnaires' disease, progression of the pneumonia continues for 4 or 5 days after institution of appropriate antibiotic therapy. Examination of pulmonary tissue infected by *Legionella* reveals a fibrinopurulent lobar pneumonia or bronchopneumonia.<sup>31</sup> Polymorphonuclear leukocytes, predominantly neutrophils, and

**FIGURE 33-1** A–D, Serial chest radiographs of a 42-year-old man with chronic lymphocytic leukemia who was admitted December 22, 1988, with Legionnaires' disease. The rapid progression of the pneumonia is evident. The radiograph dated November 14, 1988 (A) was taken when he was well.

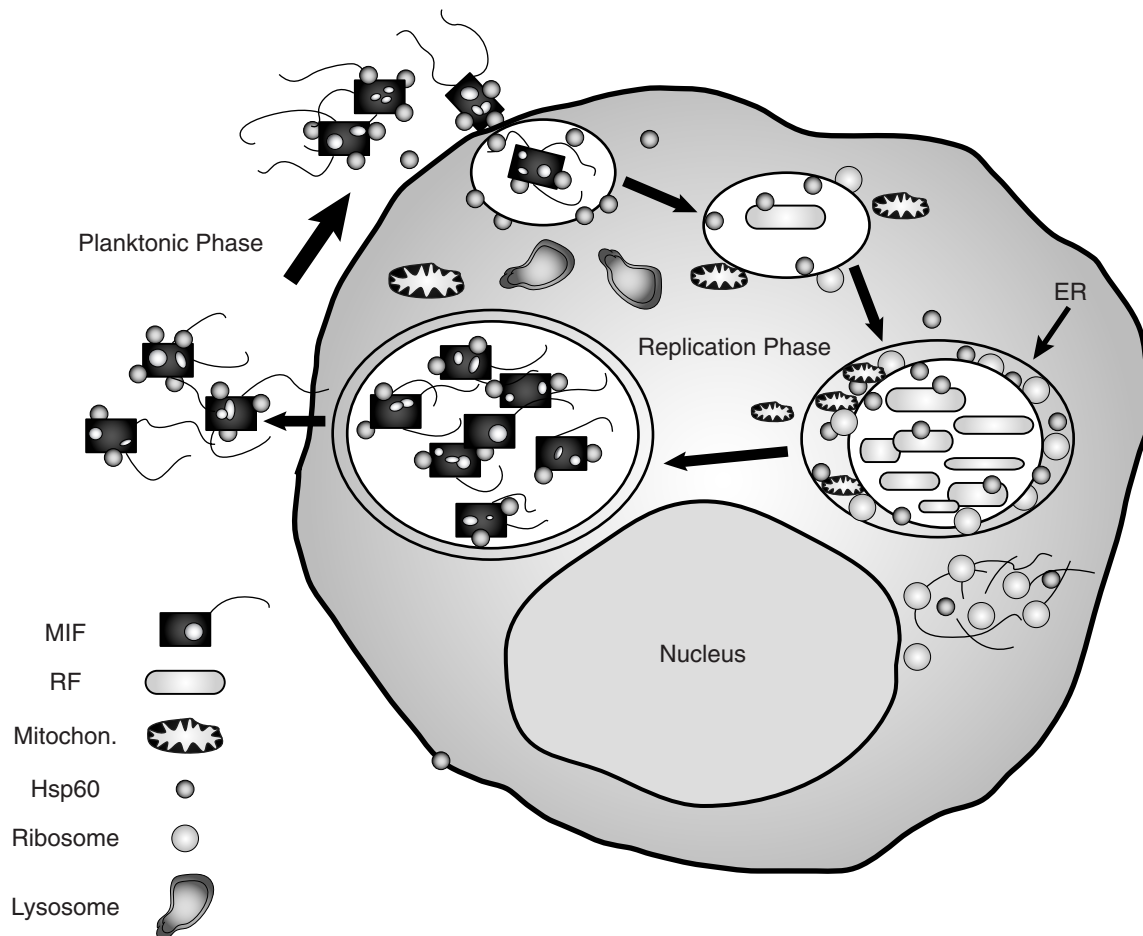

macrophages are found within the alveoli. Leukocytoclasia is a common feature. A mixed interstitial inflammatory pattern may accompany the airspace inflammation. Thrombosis of small vessels, septic vasculitis, and alveolar wall necrosis can occur.

### **PATHOGENESIS AND IMMUNITY**

The legionellae are intracellular parasites of protozoa in natural environments, and humans become infected by inhalation of aerosols containing bacteria or amoeba laden with the organisms.<sup>32</sup> In the lung, *Legionellae* are actively phagocytized by alveolar macrophages, in which they abrogate phagosome–lysosome fusion and replicate in an endosome surrounded by the endoplasmic reticulum.<sup>33</sup> It is generally believed that *Legionella* plies a common infection strategy in both natural hosts and human macrophages<sup>34</sup> as depicted in Figure 33-2. The legionellae are naturally invasive but can enter alveolar macrophages by coiling phagocytosis or following opsonization with complement or antibodies.

Once intracellular, the bacteria-laden endosome recruits small vesicles, mitochondria, and ribosomes and within 4 to 6 hours becomes enveloped by the endoplasmic reticulum, establishing the replicative endosome.<sup>33</sup> Bacterial growth initiates between 4 and 6 hours postinfection and continues in macrophages for 24 hours, at which time the macrophage disintegrates and the bacteria are released. Macrophage death is due to apoptosis that is activated early in infection.<sup>35</sup> The released bacteria are often phagocytized by other macrophages, and the cycle is repeated.

A new developmental form of *L. pneumophila* has been identified and characterized in natural hosts and in non-phagocytic HeLa cell cultures that resembles a cyst or spore.<sup>36,37</sup> Mature intracellular forms (MIFs) stain red with Gimenez stain, whereas vegetative replicating bacteria do not retain the red stain and are counterstained green.<sup>37</sup> The cystlike MIF is highly infectious, metabolically dormant, and can persist in potable water for long periods of time. In natural hosts, MIFs appear between 48 and 72 hours postinfection and are not

**FIGURE 33-2** *Legionella pneumophila* developmental cycle. *Legionella pneumophila* enters natural hosts and macrophages by phagocytosis. The bacteria are invasive of nonphagocytic cell lines. Depicted are the mature intracellular forms (MIFs) entering a host cell and contained within an endosomal membrane. Displayed on the surface of MIFs that stain red by the Gimenez stain is Hsp60, a surface-associated protein that promotes attachment and invasion. The endosome does not fuse with lysosomes and recruits vesicles, mitochondria, and ribosomes. The *Legionella*-laden endosome becomes surrounded by the endoplasmic reticulum (ER), producing a replication-proficient environment. During this period, MIFs germinate into vegetative replicative forms (RF) and no longer stain red with Gimenez stain. The bacteria initiate rounds of replication, and late in infection the RFs differentiate into the nonreplicating MIFs. Following destruction of the host cell, MIFs are released into the environment. MIFs are initially motile, but they lose motility after 24 hours and further differentiate into a planktonic cyst that can remain infectious for extended periods while between hosts.

appreciably observed in macrophages due to early apoptotic death. It has been suggested that MIFs likely represent the transmissible form of the disease and offer an explanation for why Legionnaires' disease is not a communicable disease in humans.<sup>37</sup>

It is noteworthy that in a murine model of Legionnaires' disease, inoculation of *L. pneumophila*-infected *Hartmannella vermiformis* resulted in an eight-fold increase in intrapulmonary *L. pneumophila*.<sup>38</sup> These observations are consistent with reports that *L. pneumophila* harvested from amoeba are more infectious upon reinfection than are in vitro-grown bacteria. MIFs are also approximately 100-fold more infectious than in vitro-grown bacteria. Since airborne amoebae are found in water aerosols,<sup>8</sup> they may serve as a reservoir or transmission vehicle for delivery of highly infectious MIFs to humans.

Virulence of *Legionella* is considered multifactorial and complex since the bacteria must not only establish the replicative endosome but also acquire all nutrients from the host cell, including amino acids, organic acids, iron, and other micronutrients.<sup>39,40</sup> Avirulent mutants do not replicate in macrophages and are defective in expression of transmission traits that include sensitivity to sodium chloride, osmotic resistance, motility, and surface location of heat shock protein 60 (Hsp60).<sup>41,42</sup> Genetic analysis reveals that most mutations associated with avirulence map to two chromosomal locations that encode components of a type IV secretion system. The system named Dot/Icm (defect in organelle trafficking/intracellular multiplication) delivers both DNA and proteins into host cells, but little is known about how effector proteins alter host cellular functions.<sup>43,44</sup> One of the delivered proteins, Hsp60, has been shown to block organelle trafficking when attached to latex beads, suggesting an unusual role for heat shock proteins in bacterial pathogenesis.<sup>45</sup> A functional type IV secretion system and the effectors it delivers are required early in invasion of host cells, but once the replicative phagosome is produced, the functions of the Dot/Icm proteins are dispensable.<sup>46</sup> Interestingly, if these proteins are not present in the progeny of spent cells, they are noninfectious upon reinoculation. Within the context of a developmental cycle, *Legionella* alternates between a vegetative replicative form (RF) and a planktonic MIF survival form that upon entry into a new host must germinate back into the RF.<sup>36,37</sup> The genes associated with regulation of each developmental form are in the early stages, but MIF formation does require regulators of stationary phase, such as sigma factor RpoS, RelA (produces alarmone ppGpp).<sup>47</sup>

Early studies established that immunity against *L. pneumophila* required development of a cellular immune response.<sup>48</sup> Antibodies are not effective against *L. pneumophila* because opsonized bacteria are more efficiently phagocytized. Interactions of *Legionella* with murine macrophages also induce an array of cytokines and chemokines. An interleukin-1 $\beta$  (IL-1 $\beta$ ) response is produced upon binding of the bacteria to macrophages.<sup>49</sup> Interestingly, IL-12 and interferon- $\gamma$  (IFN- $\gamma$ ) are commonly detected in serum of infected patients or in animal models, but in macrophage culture, *Legionella* specifically represses IL-12 production.<sup>50</sup> It is now believed that most of the IL-12 is produced by dendritic cells.<sup>51</sup> Among the cytokines detected in murine models or in human infection are IL-1 $\alpha$ , IL-1 $\beta$ , IL-4, IL-6, IL-12, and IL-18. The lack of viable markets for vaccines against *Legionella* has limited research initiatives in this area. In one study, vaccination of

guinea pigs with the purified major outer membrane protein OmpS protected guinea pigs against an LD<sub>100</sub> lethal challenge, whereas immunization with purified Hsp60 provided little protection.<sup>52</sup> Production of IFN- $\gamma$  has a protective effect by promoting activation of macrophages. Activated macrophages limit the intracellular replication of *Legionella* by decreasing the expression of transferrin receptors and limiting the availability of iron to the bacteria.<sup>53</sup>

*Legionella pneumophila* serves as a model system for the study of innate immunity because as an aquatic pathogen of protozoa, it has not evolved mechanisms to evade the human immune system. In this regard, human infection represents a dead end or failure in the life cycle of *Legionella* and provides an explanation for why immunocompromised people are so susceptible to infection.<sup>34</sup> Thus, whatever *Legionella* can do to interfere with the host immune system occurs by chance and not by the design of evolution.

## DIAGNOSIS

A high index of suspicion is necessary in diagnosing sporadic cases of Legionnaires' disease. Outbreaks of pneumonia usually trigger a workup for *Legionella*, so these are easier to diagnose.

Isolation of the organism from respiratory secretions is the definitive diagnostic method. Detection of *Legionella* antigen in urine by enzyme-linked immunosorbent assay (ELISA) is approximately 80% sensitive and more than 95% specific.<sup>54,55</sup> This test is readily available for *L. pneumophila* serogroup 1. Diagnostic kits are also available for detection of antigens of *L. pneumophila* 1 to 6. *Legionella* antigen is excreted in the urine for days to weeks (rarely up to 1 year) after the onset of pneumonia.

Demonstration of a fourfold rise in antibody titer between acute and convalescent serum samples using an indirect immunofluorescence whole-cell assay can also be used to diagnose Legionnaires' disease. Up to 12 weeks may be required to demonstrate a fourfold rise in antibody, so serology is not useful for the acute management of this disease. A single or static titer of 1:256 or greater is no longer considered satisfactory for the diagnosis of Legionnaires' disease.<sup>56</sup> Polymerase chain reaction (PCR) applied to respiratory secretions, pulmonary tissue, or pleural fluid is currently undergoing evaluation as a diagnostic method.<sup>57,58</sup> In particular, PCR of material obtained by throat swab is an attractive approach, but the sensitivity and specificity of such a strategy have yet to be defined.

## TREATMENT AND PROGNOSIS

Erythromycin has been considered to be the drug of choice. It should be given in a dose of 1 g intravenously every 6 hours. At this dosage, reversible ototoxicity may occur.<sup>59</sup> Rifampin (300 mg twice daily) orally should be given until clinical improvement occurs, at which time it can be discontinued. Relapses occur with treatment of less than 21 days' duration.

Azithromycin is also effective in the treatment of Legionnaires' disease.<sup>60</sup> Quinolones and doxycycline are also active against *L. pneumophila*, and they have been used to treat Legionnaires' disease.

Early administration of antibiotics (within 8 hours of admission to hospital) to patients with severe Legionnaires' disease has been associated with better outcomes.<sup>61</sup>

## PREVENTION AND CONTROL

When cases of nosocomial Legionnaires' disease are diagnosed, the potable water distribution system of the hospital should be cultured for *Legionella*. If legionella is found, heating the water to 160°F (70°C) for several days and then flushing hot water throughout all the outlets can result in temporary reduction of the concentration of *Legionella* in the water. Hyperchlorination or the addition of copper and silver ions to the water supply can also control contamination of the potable water and result in cessation of outbreaks of nosocomial Legionnaires' disease. If legionellaceae cannot be eradicated from the water supply, all organ transplant recipients and all those who are receiving corticosteroids should not drink the water and should not shower in the water. In addition, on-site or nearby cooling towers should have the coolant water cultured for *Legionella*.

Outbreaks of Legionnaires' disease onboard cruise ships and at flower shows emphasize the importance of surveillance for this infection and control of *Legionella* in a variety of water distribution systems.<sup>62</sup>

# Melioidosis

DAVID ALLAN BRETT DANCE

## INTRODUCTION

Melioidosis is the name given to any infection caused by the gram-negative bacillus *Burkholderia pseudomallei*. Previously considered an esoteric and rare disease, melioidosis has emerged over the past 20 years as an important cause of morbidity and mortality in Southeast Asia and northern Australia, and is also endemic in other tropical regions. More recently still, it has attracted attention as a potential bioweapon, and *B. pseudomallei* has been classified as a “Category B” agent by the US Centers for Disease Control.<sup>1</sup>

## ORGANISM

Melioidosis was first recognized as a fatal “glanders-like” illness in Burma in 1911 by Alfred Whitmore.<sup>2</sup> The genetic similarity of the causative organism to that of glanders, *Burkholderia mallei*, has been confirmed by modern taxonomists, supporting Whitmore’s proposal of the specific epithet *pseudomallei*. Animal and human infections with Whitmore’s bacillus were later recognized by Stanton and Fletcher in the Federated Malay States.<sup>3</sup> They considered the disease to be a zoonosis and coined the term *melioidosis*, derived from the Greek *μηλῖς* (glanders or distemper of asses). Workers in French Indochina subsequently showed that the organism was really an environmental saprophyte.<sup>4</sup> Over 400 French and American soldiers contracted the disease during the wars in Southeast Asia.<sup>5</sup> Since the mid-1970s, melioidosis has emerged as an important infection in parts of Thailand, and it is being increasingly recognized elsewhere.<sup>6,7</sup>

*B. pseudomallei* was previously classified in various genera (e.g., *Malleomyces*, *Pfeifferella*, *Actinobacillus*, *Bacillus*, *Pseudomonas*), but along with other members of ribosomal RNA (rRNA) homology group II of the genus *Pseudomonas* (e.g., *Pseudomonas cepacia*), it was assigned to the new genus, *Burkholderia*, by Yabuuchi in 1992.<sup>8</sup>

## EPIDEMIOLOGY

### Geographic Distribution

The main area of melioidosis endemicity is Southeast Asia. The disease has also been recognized as endemic to tropical Australia since 1949, possibly introduced by troops returning from endemic areas at the end of the World War II.<sup>9</sup> It is estimated that 2000 to 5000 cases occur each year in Thailand,<sup>10</sup> while up to 50 cases are diagnosed annually in both Singapore and Australia. In recent years it has become clear that the

disease is also prevalent in China<sup>11</sup> and the Indian subcontinent,<sup>12</sup> which has been the source of infection of several recent cases diagnosed in Britain.

It is likely that the true distribution of melioidosis extends beyond Southeast Asia and northern Australia. Sporadic cases have been reported from the Pacific islands, central Africa, Central and South America, and the Caribbean.<sup>6,7</sup> The disease is probably underdiagnosed in many of these regions, because relatively sophisticated laboratory facilities are necessary to confirm the diagnosis. Furthermore, reports of cases in Iran and an epizootic that occurred in France during the 1970s<sup>13</sup> suggest that infection may be transmitted in nontropical regions.

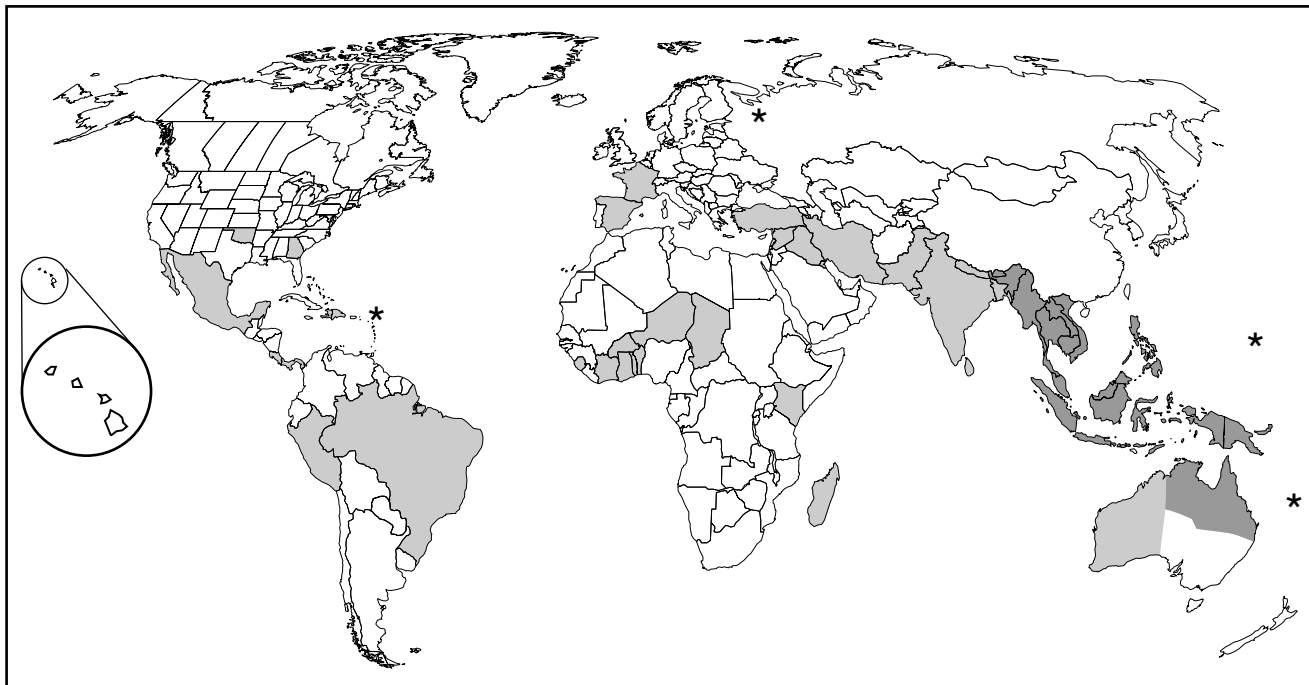

## Reservoirs and Transmission

*B. pseudomallei* is readily isolated from soil and surface water in endemic areas, particularly from rice paddies.<sup>14</sup> Using selective media it may be recovered from 68% to 78% of rice fields in Thailand.<sup>15,16</sup> Some arabinose-assimilating environmental isolates originally thought to be *B. pseudomallei* have now been assigned to a new, avirulent species, *Burkholderia thailandensis*.<sup>17</sup> *B. pseudomallei* is thought to persist in clay layers during the dry season, from which it recolonizes the surface mud and water during the rainy season.<sup>18</sup> The physical, chemical, and biologic factors that influence environmental colonization with *B. pseudomallei* are poorly understood.<sup>19</sup>

Humans and a wide range of animals are thought usually to become infected by inoculation or contamination of wounds or mucosae with soil or surface water, although a specific exposure incident is only identified in 6% to 25% of cases.<sup>20,21</sup> Infections occurred in a disproportionate number of helicopter crewmen during the Vietnam War, possibly through inhalation of aerosols generated by the rotors.<sup>22</sup> Two recent outbreaks in Australia have been traced to potable water supplies, although the mode of transmission was uncertain.<sup>23,24</sup> There is no evidence that ingestion or insect vectors play a role in transmission. Although melioidosis has been observed in a wide range of animal species (including rodents, primates, sheep and goats, pigs, cattle, horses, deer, dogs and cats, dolphins, koalas, kangaroos, camels, crocodiles, and birds), transmission from animals to humans has rarely been reported,<sup>25</sup> and person-to-person spread is also extremely uncommon.<sup>26</sup> Iatrogenic infection from contaminated injections and laboratory-acquired infections have also been reported occasionally, resulting in the classification of *B. pseudomallei* as a containment level 3 pathogen.

## Descriptive Epidemiology

Melioidosis predominantly affects people in regular contact with soil and water (e.g., rice farmers in Southeast Asia and aboriginals in Australia). In northeastern Thailand, melioidosis accounts for 18% of community-acquired septicemia,<sup>27</sup> and in the Northern Territory of Australia it is the commonest cause of fatal community-acquired sepsis.<sup>21</sup> In a review of the epidemiology of culture-positive melioidosis seen over a 5-year period in Ubon Ratchathani in northeastern Thailand, the average annual incidence was estimated as 4.4 per 100,000 population, with evidence of space-time clustering.<sup>20</sup>

*Burkholderia pseudomallei* and like organisms

- Main endemic areas
- ★ Sporadic isolates

All age groups were affected, with the peak incidence occurring from age 40 to 60 years. The male-female ratio is only 3:2 in Thailand, but is much higher in Australia and Singapore, probably because of differences in exposure to soil during rice farming. The reported incidence is up to tenfold higher in parts of Australia, probably reflecting better ascertainment. Wherever the disease occurs, it is markedly seasonal, approximately 75% of cases presenting during the rainy season, with the highest incidence occurring during especially heavy monsoons.<sup>21</sup> Most cases appear to be recently acquired,<sup>28</sup> but the disease may remain latent for as long as 29 years.<sup>29</sup> The presence of underlying diseases, such as diabetes mellitus, chronic renal failure, immunosuppressive treatments including steroids, thalassemia, chronic liver disease, chronic lung disease (including cystic fibrosis), and kava consumption, which are found in 60% to 80% of cases,<sup>20,21,30,31</sup> is an important risk factor for melioidosis. The association with diabetes mellitus is particularly strong and may increase the relative risk of infection by up to 100-fold.<sup>20</sup> Perhaps surprisingly, there is no evidence that human immunodeficiency virus infection predisposes to melioidosis.

## DISEASE

The clinical spectrum of *B. pseudomallei* infection is extremely broad, and melioidosis has been referred to as “the remarkable imitator.”<sup>32</sup> The majority of infections are subclinical, although melioidosis may run a fulminant, rapidly fatal course, particularly in the immunocompromised. None of the clinical classifications of melioidosis is entirely satisfactory.

Infections may be acute or chronic and localized or disseminated, but one form of the disease may progress to another and individual patients are often difficult to categorize. Several reviews have summarized the clinical manifestations of melioidosis.<sup>2,3,5,21,22,27,33–35</sup>

## Mild and Subclinical Infections

In endemic areas such as northeastern Thailand, 80% of children have antibodies to *B. pseudomallei* by the time they are 4 years old,<sup>36</sup> yet melioidosis is uncommon, so the majority of infections are presumably mild or asymptomatic. A flulike illness associated with seroconversion has been reported from Australia.<sup>37</sup>

## Latent Infections

Melioidosis is unusual for a bacterial infection in that long periods of latency have been observed before the disease has become clinically apparent.<sup>29</sup> Recrudescence infections in veterans of the Vietnam War have given rise to the nickname “Vietnamese time bomb.”<sup>38</sup> Relapses usually occur at times of intercurrent stress (e.g., other acute infections, burns or trauma, malignancies, diabetes mellitus), when cellular immunity is likely to be suppressed. The sites and mechanisms of persistence are unknown, although clinically silent, chronic, localized foci of melioidosis in the lung, liver, or spleen have been reported in animals. The proportion of seropositive patients who harbor latent infection, and are therefore at risk of relapse, is also uncertain.

### Septicemic Meliodosis

Approximately 50% to 60% of cases of culture-positive meliodosis have positive blood cultures.<sup>20,21</sup> Most of these present clinically as community-acquired sepsis syndrome, with a short history (median, 6 days; range, 1 day to 2 months) of high fever and rigors, although some have a less acute, typhoidal illness with a swinging fever, often associated with profound weight loss.<sup>27</sup> Patients with multiple, noncontiguous foci of infection, which probably reflect bacteremia at some stage, behave similarly. Only half have evidence of a primary focus of infection, usually in the lung or skin and subcutaneous tissues. Confusion, stupor, jaundice, and diarrhea may also be prominent features. Initial investigations usually reveal anemia, a neutrophil leukocytosis, coagulopathy, and evidence of renal and hepatic impairment. Such patients often deteriorate rapidly, developing widespread metastatic abscesses, particularly in the lungs, liver, and spleen, and metabolic acidosis with Kussmaul's breathing. Once septic shock has supervened, the untreated mortality approaches 95%, with many patients dying within 48 hours of hospital admission. Other poor prognostic features include absence of fever, leukopenia, azotemia, and abnormal liver function tests.<sup>27</sup>

If the patient survives this acute phase, the manifestations of the multiple septic foci which result from bacteremic dissemination become prominent. Any site or tissue may be involved, but the most common foci are the lungs, liver, spleen, prostate, and skin and soft tissues. An abnormal chest radiograph is found in 60% to 80% of patients, the most common pattern being widespread, nodular shadowing<sup>39</sup> (Fig. 34-1). Multiple liver and splenic abscesses are also common<sup>40</sup> (Fig. 34-2). Cutaneous pustules or subcutaneous abscesses occur in 10% to 20% of cases<sup>27</sup> (Fig. 34-3). Secondary lesions may occur in any other tissue or organ (e.g., kidneys, bones and joints, brain). "Neurological meliodosis," characterized by peripheral motor weakness, brain stem encephalitis, aseptic meningitis, and respiratory failure, is now thought to reflect direct invasion of the central nervous system rather than being toxin-mediated.<sup>21,41</sup>

**FIGURE 34-1** Chest radiograph of a patient with septicemic meliodosis showing multiple foci of consolidation ("blood-borne pneumonia"). (From Dance DAB: Meliodosis. In Cook G [ed]: Manson's Tropical Diseases, 20th ed. London, WB Saunders, 1996, pp 925–930.)

**FIGURE 34-2** Abdominal ultrasound showing multiple liver abscesses in a patient with septicemic meliodosis ("Swiss cheese liver"). A similar picture may be seen in the spleen. (From Dance DAB: Meliodosis, glanders, and tularaemia. Med Int 107:4508–4511, 1992.)

### Localized Meliodosis

The most common site of localized meliodosis is the lung, usually in the form of a subacute cavitating pneumonia accompanied by profound weight loss, which is often confused with tuberculosis<sup>42</sup> (Fig. 34-4). Relative sparing of the apices and the infrequency of hilar adenopathy may help to distinguish the two.<sup>39</sup> There is a predilection for the upper lobes, although any lung zone may be affected. Complications include pneumothorax, empyema, and purulent pericarditis, and ultimately progression to septicemia.

Acute suppurative parotitis (Fig. 34-5) is a characteristic manifestation of meliodosis in Thai children, accounting for

**FIGURE 34-3** Multiple pustules on the legs of a rice farmer with nephrotic syndrome, treated with steroids. Gram stain of pus revealed numerous *Burkholderia pseudomallei* organisms. (From Dance DAB: Meliodosis, glanders, and tularaemia. Med Int 107:4508–4511, 1992.)

**FIGURE 34-4** Chest radiograph of a patient with localized pulmonary melioidosis showing extensive consolidation and cavitation. (From Pitt TL, Dance DAB: Melioidosis and *Pseudomonas pseudomallei*. Public Health Lab Serv Microbiol Digest 8:127–130, 1991.)

**FIGURE 34-5** Child with acute suppurative parotitis. In this case the overlying skin is involved, an abscess has ruptured into the auditory canal, and there is facial nerve palsy. The child was also septicemic. (From Dance DAB: Melioidosis, glanders, and tularaemia. Med Int 107:4508–4511, 1992.)

approximately one-third of pediatric cases,<sup>43,44</sup> but has rarely been reported elsewhere. This strong age-site association probably reflects ascending infection after oral contamination with muddy water. Most cases are unilateral and result in parotid abscesses that require surgical drainage, although they may rupture spontaneously into the auditory canal. Facial nerve palsy and septicemia are rare complications.

Although the lung and parotid are the most common foci for localized *B. pseudomallei* infection, any other organ or tissue may be affected. Well-described examples include cutaneous and subcutaneous abscesses, lymphadenitis, osteomyelitis and septic arthritis, liver or splenic abscesses, cystitis, pyelonephritis, prostatic abscesses, epididymo-orchitis, keratitis, and brain abscesses.

### Pathology

*B. pseudomallei* is essentially a pyogenic organism, but lesions of melioidosis may vary from an acute, necrotizing inflammation with abscess formation to a chronic granulomatous inflammation, depending on the duration of the infection, and sometimes a mixed picture is seen.<sup>45</sup> It is difficult to make a specific histopathologic diagnosis, but features which may be helpful include the presence of intracellular “globi” of gram-negative bacilli combined with giant cells against a background of acute necrotizing inflammation.<sup>46</sup>

### PATHOGENESIS

The pathogenesis of melioidosis is poorly understood and until recently had been relatively little studied. The outcome of infection with *B. pseudomallei* depends on the balance between the host's immune system, the virulence of the infecting strain, and the size and route of the initial inoculum. Abscesses or granulomas occur at the site of primary infection, from which invasion of the bloodstream may ensue leading to septicemia and metastatic seeding of other tissues. A high level of bacteremia ( $> 50$  CFU/mL) is associated with a fatal outcome.<sup>47</sup>

### Bacterial Virulence Factors

The advent of molecular techniques, including the sequencing of the *B. pseudomallei* genome, as well as comparison with the closely related, avirulent *B. thailandensis*, have greatly facilitated studies of *B. pseudomallei* virulence. The organism possesses several potential virulence determinants and strains of the organism undoubtedly vary in virulence.<sup>48</sup> Lipopolysaccharide (LPS) is presumably important during septicemia, although the biologic effects of *B. pseudomallei* LPS differ from those of enterobacterial LPS.<sup>49</sup> An extracellular polysaccharide capsule is undoubtedly a key virulence factor, although its precise role remains to be defined.<sup>50</sup> Other possible virulence determinants include a heat-labile, lethal exotoxin with a molecular weight of approximately 31 kD, which appears to act by inhibition of synthesis of macromolecules<sup>51</sup>; various other toxins and enzymes (e.g., hemolysin, lecithinase, lipase, and proteases<sup>52</sup>); a siderophore (malleobactin)<sup>53</sup>; flagella<sup>54</sup>; acid phosphatase<sup>55</sup>; and type III secretion systems.<sup>56</sup>

There is increasing evidence that *B. pseudomallei* is able to survive intracellularly,<sup>57</sup> which probably contributes to the

recalcitrant nature of melioidosis, its potential for long periods of latency, and its tendency to relapse.<sup>58</sup> Spread between cells appears to occur in a manner similar to, but different from, that which occurs with *Listeria monocytogenes*, involving actin rearrangement into a comet tail appearance within membrane protrusions, and leading to cell death through apoptosis.<sup>59</sup>

### Host Defense

As already mentioned, clinically apparent melioidosis is an opportunistic infection. There is some evidence that innate, humoral, and cell-mediated immunity all contribute to defense against the disease. Evidence from studies in experimental animals suggests that antibodies to the exotoxin, LPS, flagellin, flagellin-LPS conjugates, and capsular polysaccharides may all have some protective effect. In human infections, the level of antibody to O-PSII, but not O-PSI, was significantly higher in patients who survived melioidosis than in those who died.<sup>60</sup> Production of interferon-gamma appears to be particularly important in protection in some mouse models.<sup>61</sup> The fact that C57BL/6 mice are considerably more resistant to infection by *B. pseudomallei* than BALB/c mice also suggests a role for cellular immunity in host defense.<sup>62</sup> On the other hand, an overaggressive host response may actually contribute to pathogenesis, and raised levels of several pro-inflammatory cytokines have been found to be associated with a poor outcome in human melioidosis.<sup>63–65</sup>

### DIAGNOSIS

Melioidosis is difficult to diagnose on clinical grounds alone, so, where possible, laboratory confirmation by detection of *B. pseudomallei* or of corresponding antibodies should be sought. This requires relatively sophisticated facilities, which are not available in many endemic areas. Because of the potential for latency, the diagnosis should be considered in any patient who has ever visited an endemic area who presents with septicemia or abscesses, particularly if there is evidence of an underlying disease such as diabetes mellitus.

### Microscopy and Culture

The organism should be sought in blood, pus, sputum, urine, or any other specimen appropriate to the clinical presentation. Microscopy of a gram-stained smear may reveal bipolar or unevenly staining gram-negative rods, but this has a low specificity and sensitivity. Direct immunofluorescent microscopy may be helpful in endemic areas, but is not widely available.<sup>66</sup> Isolation and identification of *B. pseudomallei* is diagnostic, since asymptomatic carriage has never been reported. The organism grows readily on most laboratory media, although it may take 48 hours or more to develop characteristic colonial morphology. The sensitivity of culture may be increased by the use of selective media.<sup>67</sup> Culture of a throat swab alone using these selective techniques has an overall sensitivity of 36% for the diagnosis of melioidosis (79% in sputum-positive patients), which is particularly useful in children or others who cannot produce sputum.<sup>68</sup> Identification of cultures may be conducted using conventional biochemical tests, commercial kits, or agglutination, but may be delayed or incorrect because many microbiologists are

not familiar with the characteristics of the organism. Consequently, if melioidosis is suspected, the laboratory should always be warned to ensure that appropriate techniques and containment measures are employed.

### Detection of Antigens and Nucleic Acids

Several rapid diagnostic techniques for the detection of *B. pseudomallei* antigens and nucleic acids have been developed, but most of these currently have suboptimal sensitivity when used directly on clinical samples and are not widely available.<sup>69,70</sup> Techniques like latex agglutination are, however, useful for rapid identification of the organism in plate or broth cultures.<sup>71,72</sup>

### Detection of Antibodies

The serodiagnostic test most widely used in endemic areas is an indirect hemagglutination (IHA) test, which detects IgM antibodies to crude heat-stable antigens (probably predominantly LPS).<sup>73</sup> The test is poorly standardized, and there is considerable interlaboratory variation between the titers regarded as positive. Both false negatives and false positives are seen, the latter being a particular problem in endemic areas as a result of high background seropositivity. Nonetheless, a single high titer (>1:40) in someone from a nonendemic area, or a rising titer, may be diagnostically useful. Enzyme-linked immunosorbent assays (ELISAs), which detect IgG antibodies, appear to give similar results. Assays which detect specific IgM (indirect immunofluorescence, ELISA) correlate better with disease activity,<sup>74–77</sup> and are thus more useful in endemic areas and, along with measurement of C-reactive protein,<sup>78</sup> in follow-up of patients on treatment. A number of assays employing more purified antigens have been reported to have better sensitivity and specificity than the IHA test,<sup>79,80</sup> but none of these tests have been subjected to a large scale, multicenter analysis.

### TREATMENT AND PROGNOSIS

#### Supportive Treatment

Patients with septicemic melioidosis usually require aggressive supportive treatment and should ideally be managed in an intensive care unit. Particular attention should be paid to correction of volume depletion and septic shock, respiratory and renal failure, and hyperglycemia or ketoacidosis. Abscesses should be drained whenever possible.

#### Specific Treatment

*B. pseudomallei* is intrinsically resistant to many antibiotics, including aminoglycosides and early  $\beta$ -lactams. A complete lack of response to penicillin and gentamicin, a combination often used in the empirical treatment of septicemia in the tropics, is characteristic of melioidosis.<sup>27</sup>

Until the mid-1980s, various empirical combination regimens were used to treat melioidosis, usually including a tetracycline, chloramphenicol, and co-trimoxazole. Several recent studies, which have been well summarized elsewhere,<sup>35,81</sup> have provided a sound evidence base for the treatment of severe melioidosis. Treatment comprises two phases, an acute

phase, the aim of which is to reduce mortality, and an eradication phase, the aim of which is to reduce the risk of relapse. The acute mortality of acute severe melioidosis can be substantially reduced by newer  $\beta$ -lactam agents such as ceftazidime, imipenem, and cefoperazone-sulbactam, with or without co-trimoxazole.<sup>82–86</sup> Very recently, dramatic success has been achieved in Darwin, northern Australia, using meropenem plus co-trimoxazole with adjunctive G-CSF, the mortality from melioidosis septic shock falling from 95% to 10%.<sup>87</sup> This work needs repeating in a randomized, prospective study. Ceftazidime (120 mg/kg/day), imipenem, or meropenem (50 mg/kg/day) is currently the treatment of choice and should be given for 2 to 4 weeks according to the clinical response. Amoxicillin-clavulanate therapy is associated with a higher failure rate,<sup>88</sup> and ceftriaxone and cefotaxime should not be used.<sup>89</sup> Unfortunately, all these new antibiotics are extremely expensive, and so practitioners in many endemic areas will have to continue using chloramphenicol succinate (100 mg/kg/day), doxycycline (4 mg/kg/day), and co-trimoxazole (trimethoprim 10 mg/kg/day and sulfamethoxazole 50 mg/kg/day), either individually or in combination, which are known to give inferior outcomes.

Following parenteral treatment, prolonged oral antibiotics are needed to prevent relapse, which occurs in up to 23% of patients,<sup>28,58</sup> and is more common in patients with more severe disease. This can be reduced to less than 10% if antibiotics are given for a total of 20 weeks.<sup>90</sup> The combination of chloramphenicol (40 mg/kg/day), doxycycline (4 mg/kg/day), and co-trimoxazole (10 mg plus sulfamethoxazole 50 mg/kg/day) has been associated with a lower relapse rate than amoxicillin and clavulanate (60 mg amoxicillin plus clavulanic acid 15 mg/kg/day), although this may have been accounted for by differences in compliance, so either regimen is probably adequate.<sup>90</sup> Amoxicillin and clavulanate is preferable in children and in pregnant or lactating women because of lower toxicity. The fluoroquinolones, with or without azithromycin, and doxycycline alone are all associated with unacceptable relapse rates.<sup>91–93</sup> It is possible that the chloramphenicol component of the regimen is not necessary,<sup>93</sup> and further prospective studies are needed to determine whether co-trimoxazole alone is adequate for eradication.<sup>21,87</sup> In patients with mild localized disease, the preceding oral regimens may be used, although the optimal agents and duration of treatment remain to be defined.

## Outcome and Follow-up

Even with optimal treatment, the mortality from acute severe melioidosis is high (30% to 47%). In patients who survive, there is often chronic morbidity resulting both from the disease itself and the underlying conditions. Patients require long-term follow-up to detect relapse. Susceptibility tests should be carried out on isolates obtained during or after treatment, since resistance may emerge in 5% to 10% of cases.<sup>94</sup>

## PREVENTION AND CONTROL

*B. pseudomallei* is ubiquitous in the environment in endemic areas, so it is difficult for those whose occupations involve soil and water contact to avoid exposure. It might be worthwhile for those particularly at risk (e.g., diabetic patients)

to avoid rice farming, or use hand and foot protection, although the effectiveness of this has not been evaluated. Elimination of the organism from soil using disinfectants was attempted in the French outbreak,<sup>13</sup> but is probably futile. There is no *B. pseudomallei* vaccine licensed for human use, although experimental vaccines are under development and have been used in animals.<sup>95</sup> The organism should be handled in containment level 3 facilities in the laboratory. Patients should ideally be nursed in standard isolation, although person-to-person spread is very rare.

# Diphtheria

MELINDA WHARTON

## INTRODUCTION

Diphtheria is caused by infection with *Corynebacterium diphtheriae*, a gram-positive bacillus. Toxigenic strains of *C. diphtheriae* produce a powerful exotoxin that is responsible for the most severe manifestations of the disease.

Prior to the introduction of effective childhood vaccination programs, diphtheria was a major cause of childhood mortality. In 1884, Löffler reported isolation of the organism from patients with diphtheria and demonstration of its pathogenicity in animals. He hypothesized that a potent poison was formed at the site of the local lesion because the organism was usually found only in the site of inoculation in the respiratory tract. In 1888, Roux and Yersin reported that sterile filtrates from cultures of the diphtheria bacillus were lethal to guinea pigs, with development of lesions identical to those found in animals infected with the organism. This was followed by the demonstration of immunity in animals that had received iodine-treated toxin, and the passive transfer of this immunity to other animals by Behring in 1890. In 1894, Roux and Martin used equine antitoxin for treatment of children, with dramatic reduction in mortality. The first vaccines were mixtures of toxin and antitoxin; these were replaced by diphtheria toxoid in the 1920s.

The organism is usually transmitted by direct person-to-person contact. Both symptomatic persons with diphtheria and asymptomatic carriers can transmit the organism, although symptomatic persons are thought to be more highly infectious than carriers. Transmission by fomites may occur, and milk-borne outbreaks have been reported.

In temperate climates, epidemics of respiratory diphtheria are seen in susceptible populations, with a seasonal increase in the fall and winter. Mortality rates of 5% to 10% are typically reported. In tropical climates, cutaneous infection is thought to typically occur repeatedly in childhood, conferring immunity. Because toxin is poorly absorbed from cutaneous sites, systemic manifestations of diphtheria toxin are less commonly seen in the cutaneous form.

## AGENT

*Corynebacteria* are taxonomically related to the mycobacteria and *Nocardia*. *C. diphtheriae* is a pleomorphic, non-motile, gram-positive bacillus. A selective medium containing tellurite is essential for primary isolation. Four biotypes—gravis,

mitis, intermedius, and belfanti—can be distinguished based on colonial morphology on tellurite blood agar and biochemically.<sup>1</sup>

Although other virulence factors exist, the most significant virulence factor is diphtheria toxin, a 58-kD protein produced by strains carrying  $\beta$ -corynebacteriophage. The phage encodes the toxin, and nontoxigenic strains can be converted to toxin production by this phage. Toxin production is controlled by a regulatory protein, diphtheria toxin regulatory protein (DtxR), which is encoded by the bacterial chromosome. Toxin production is inhibited by iron, which binds to DtxR. The DtxR-iron complex then binds to the diphtheria toxin gene operator, repressing synthesis of toxin.<sup>2</sup>

Rarely, other *Corynebacterium* species (*C. pseudotuberculosis* and *C. ulcerans*) can produce toxin. Sequence analysis of 16S ribosomal RNA has demonstrated that these species are closely related to *C. diphtheriae*.<sup>3</sup>

## EPIDEMIOLOGY

Diphtheria occurs worldwide, but where effective childhood immunization programs have been implemented, dramatic reductions in diphtheria morbidity and mortality have resulted. In industrialized countries, routine immunization of infants and young children in the 1940s and 1950s led to dramatic reductions in diphtheria incidence. Although clinical diphtheria is now rare in most developed countries, circulation of *C. diphtheriae* may persist in selected populations within those countries. Circulation of toxigenic *C. diphtheriae* has been documented in Canada and in the United States.<sup>4,5</sup>

In developing countries, diphtheria toxoid was included in the Expanded Programme on Immunization beginning in the 1970s. Vaccination coverage of infants with three doses of diphtheria toxoid in developing countries rose from 5% in 1974 to 46% by 1985 and 79% by 1992.<sup>6</sup> From 70,000 to 90,000 cases of diphtheria were reported each year during the 1970s to the World Health Organization (WHO); by the 1990s, this had decreased to 22,000 to 27,000 cases each year, representing a decrease worldwide of about 70% over a 20-year period. The reduction in reported cases of diphtheria globally during this period was largely due to reductions in reported cases of diphtheria in developing countries.<sup>7</sup>

A major diphtheria epidemic began in the Russian Federation in 1990 and subsequently spread throughout the former Soviet Union. By early 1996, approximately 125,000 cases and 4000 deaths had been reported in the new independent states of the former Soviet Union.<sup>8</sup> Although the factors that led to this epidemic are not completely understood, delayed immunization of young children and lack of routine booster immunization of adults contributed to susceptibility of the population. Population movements following the dissolution of the Soviet Union facilitated spread within the new independent states. Molecular typing has demonstrated that the outbreak was associated with the emergence of an epidemic clone of *C. diphtheriae* biotype gravis in Russia, although other strains circulated concurrently.<sup>9</sup> Russian-manufactured diphtheria toxoid was used throughout the Soviet Union prior to the country's dissolution; in several case-control studies, the vaccine was demonstrated to be highly effective in prevention of diphtheria.<sup>10,11</sup> In response to the epidemic, vaccine coverage of both

children and adults has increased in most countries of the former Soviet Union, and the incidence of disease has been dramatically reduced.

Diphtheria epidemics among adolescents and young adults have also been reported in a number of developing countries. Prior to the introduction of routine immunization programs, diphtheria was predominantly a disease of young children in developing countries, with little disease among those 15 years of age and older.<sup>6</sup> As vaccination programs are introduced, the incidence of disease decreases among the children targeted by those programs and the average age of patients with diphtheria increases.<sup>12</sup> Outbreaks in Jordan, Lesotho, Algeria, China, and Ecuador have been reported.<sup>6,13–15</sup> The common features of these epidemics were that they occurred following a period of high immunization coverage among young children and that cases of diphtheria were predominately reported among adolescents and young adults, populations not covered by the immunization program.

In tropical and subtropical climates, *C. diphtheriae* was a common cause of cutaneous infection prior to the introduction of vaccination programs. In these areas, repeated exposure early in life was thought to result in immunity, and severe manifestations of diphtheria were infrequent.<sup>16,17</sup> Cutaneous diphtheria is thought to serve as the primary reservoir of *C. diphtheriae* in endemic areas where poverty, crowding, and poor hygiene are prevalent. In temperate climates, respiratory diphtheria exhibits a marked seasonality, with seasonal increases in the autumn and winter.

Group A *Streptococcus* is frequently isolated from cases of both respiratory and cutaneous diphtheria. It is unknown if one infection predisposes to the other, or if they are frequently co-isolated, because both infections may be associated with similar risk factors.

## DISEASE

Following an incubation period of 2 to 5 days, the illness begins with malaise, sore throat, anorexia, and low-grade fever. The hallmark of respiratory diphtheria is the pseudomembrane (Fig. 35-1), which may be seen in the posterior oropharynx, and may extend into the larynx or trachea or upward into the nose. The pseudomembrane is composed of fibrin, cellular debris, and bacteria and may be white, gray, or black, and is typically firmly adherent, resulting in bleeding if forcibly removed. The membrane usually begins on the tonsils or posterior pharynx, but can spread upward into the nasopharynx or in severe cases into the trachea and bronchi. Soft-tissue swelling of the neck results in the so-called bull-necked appearance. In vaccinated persons, the membrane may be follicular and nonconfluent.

The most serious complications of diphtheria are respiratory obstruction, if the membrane is extensive, and complications due to distant effects of the toxin, most commonly myocarditis or neuropathy. Myocarditis typically occurs 7 to 14 days after onset of disease, but may occur as early as the first week or as late as 6 weeks after onset of illness. Electrocardiographic abnormalities may be detected in the absence of clinical signs or symptoms of myocardial involvement. The most common electrocardiographic abnormalities are flattening and inversion of T waves, ST-segment changes,

**FIGURE 35-1** Pseudomembrane in a patient with respiratory diphtheria. (Courtesy of Dr. Peter Strebel, Centers for Disease Control and Prevention, Atlanta, GA.)

and conduction abnormalities, including complete heart block. The prognosis appears to be worse in cases of diphtheria myocarditis with conduction disturbances or ventricular ectopy.<sup>18,19</sup> Use of artificial pacemakers may be required, but even with ventricular pacing, a high mortality has been reported among patients with severe conduction abnormalities.<sup>20,21</sup> Permanent cardiac damage due to diphtheria myocarditis is rare, but recovery may be prolonged. Pathologically, scattered foci of hyaline and granular degeneration are seen early in the course, followed by fibrosis.

Neuropathy may be seen either early or late in the course of illness. Palatal neuropathy and other cranial nerve palsies are often seen early in the course—as early as the first week of illness—while ocular palsies, diaphragmatic paralysis, and paralysis of limbs are generally seen later in the course of illness. Electrophysiologic studies demonstrate slowing of conduction, prolongation of distal motor latency, and, in severe cases, conduction block. Diaphragmatic paralysis may necessitate ventilatory support. If the patient survives, complete recovery is expected. Pathologic changes include segmental demyelination of nerve fibers within sensory ganglia and demyelination of adjacent peripheral nerves and anterior and posterior roots.

Other complications include renal failure, thrombocytopenia, and coagulation abnormalities. Disseminated intravascular coagulation may occur in severe cases.

Cutaneous diphtheria may occur as a secondary infection following impetigo, other skin infections, or injury (Fig. 35-2). Primary diphtheria typically begins as a vesicle or pustule that progresses to a punched-out ulcer, most commonly seen on the extremities. Lesions may be single or multiple. The ulcer initially is painful and covered with a dark pseudomembrane, but later becomes anesthetic. Healing usually occurs spontaneously over 6 to 12 weeks, but the course may be more prolonged.<sup>22</sup> Complications due to systemic absorption of diphtheria toxin may be seen, but are uncommon. Cutaneous diphtheria is more common in tropical and subtropical areas than in temperate areas.

**FIGURE 35-2** Cutaneous diphtheria in a child with nasal diphtheria. (Courtesy of Dr. Linda Quick, Centers for Disease Control and Prevention, Atlanta, GA.)

## PATHOGENESIS

Diphtheria toxin is a 58-kD protein comprising 535 amino acid residues. It is synthesized as a single polypeptide but in its active form is proteolyzed to two polypeptide chains linked by a disulfide bond. The C-terminal B fragment (345 residues) contains the transmembrane and receptor-binding domains, and the N-terminal A fragment (190 residues) contains the catalytic domain. On the cell surface, diphtheria toxin binds to heparin-binding epidermal growth factor precursor, and the toxin-receptor complex undergoes receptor-mediated endocytosis. The A fragment is then translocated across the endocytic membrane into the cytosol. In the acidic environment of the endosome, protonation of specific residues within the transmembrane domain facilitates penetration of the endoplasmic membrane.<sup>23</sup> Once in the cytosol, the catalytic domain catalyzes the transfer of adenosine diphosphate (ADP)-ribose from nicotinamide adenine dinucleotide (NAD) to elongation factor-2, halting protein synthesis and resulting in cell death.<sup>24</sup> Although diphtheria toxin is the major virulence factor in *C. diphtheriae*, other virulence factors exist. Nontoxigenic *C. diphtheriae* strains can cause typical respiratory diphtheria with pseudomembrane, although toxin-related complications such as myocarditis and neuropathy are not seen. Invasive disease due to nontoxigenic strains of *C. diphtheriae* is well documented.<sup>25</sup>

## DIAGNOSIS

The diagnosis of diphtheria is often made initially on clinical grounds. Because of the importance of early treatment with diphtheria antitoxin, clinicians should not wait for laboratory confirmation to initiate treatment.

The diagnosis is confirmed by isolation of *C. diphtheriae* from the site of infection. Use of a selective culture medium containing tellurite is essential to primary isolation; therefore, the clinical laboratory must be alerted that diphtheria is suspected.

For evaluation of patients with suspected respiratory diphtheria, both nasopharyngeal and throat swabs should be obtained. Nasopharyngeal swabs are obtained by inserting the swab through one nostril beyond the anterior nares. The swab is gently advanced along the floor of the nasal cavity under the middle turbinate until the pharyngeal wall is reached. Force must not be used to overcome any obstruction. For throat swabs, the pharynx should be clearly visible and well illuminated and the tongue depressed with an applicator. The throat is swabbed without touching the tongue or the buccal mucosa. The membrane should be rubbed vigorously, with slight pressure and a rotating movement applied to the swab.

The edge of the membrane should be lifted and the area beneath it swabbed. For suspected cases of diphtheria infection of nonrespiratory sites, the lesions should be cleansed with sterile normal saline and any crusted material removed, and the swab pressed firmly into the lesion.<sup>1</sup>

Once isolated, the organism should be characterized by biotype and evaluated for production of toxin. The standard method of toxigenicity testing is the Elek immunoprecipitation test. A polymerase chain reaction (PCR) assay for the *tox* and *dtxR* genes has been developed. PCR may be performed directly on clinical specimens, providing a rapid confirmatory test.<sup>26</sup>

The differential diagnosis of respiratory diphtheria includes bacterial and viral pharyngitis, infectious mononucleosis, Vincent's angina, acute epiglottitis, and peritonsillar abscess.

## TREATMENT AND PROGNOSIS

The mainstay of treatment of diphtheria is diphtheria antitoxin. Because diphtheria antitoxin does not neutralize intracellular diphtheria toxin, it is essential that it be given as early in the course of illness as possible; prognosis clearly worsens the later in the course of illness that antitoxin is administered. Often it is necessary to make the decision to administer antitoxin on clinical grounds, before laboratory confirmation is available.

Available preparations of diphtheria antitoxin are of equine origin and, as with any heterologous serum, may produce immediate or delayed reactions. A history of prior horse serum exposure or allergy should be obtained and the patient tested for hypersensitivity by skin or eye testing prior to administration of the product. During hypersensitivity testing or infusion of diphtheria antitoxin, a 1:1000 solution of epinephrine should be available and ready for emergency use if needed.

For skin testing, 0.1 mL of a 1:100 dilution of diphtheria antitoxin in physiologic saline is injected intracutaneously. A wheal 1 cm or more in diameter at 20 minutes indicates sensitivity. In persons with a history of allergy to equine serum, 0.05 mL of a 1:1000 dilution should be administered. A negative test does not preclude the occurrence of serum reactions.

For eye testing, one drop of a 1:10 dilution of diphtheria antitoxin in physiologic saline is instilled in the lower lid of one eye and one drop of physiologic saline is instilled in the other eye for comparison. At 20 minutes, conjunctivitis and lacrimation indicate sensitivity, and the eye should be treated with one drop of a 1:100 solution of epinephrine.

If there is no history of hypersensitivity to equine serum and the sensitivity test is negative, the total recommended dose of antitoxin should be given without delay. The dose is determined by the site and extent of local disease and the severity and duration of illness. For anterior nasal diphtheria, 10,000 to 20,000 units of diphtheria antitoxin is recommended, with increasing doses for the tonsillar form (15,000–25,000 units), pharyngeal or laryngeal diphtheria of 48 hours or less duration (20,000–40,000 units), nasopharyngeal disease (40,000–60,000 units), and extensive disease of greater than 3 days' duration or with brawny swelling of the neck (80,000–120,000 units). The preferred route

of administration is intravenous because peak antitoxin levels may not be reached for several days following intramuscular administration. The patient should be carefully monitored during administration of antitoxin and the infusion stopped if there are signs of shock.

If the patient is sensitive to horse serum, the indications for use of diphtheria antitoxin should be re-evaluated. If antitoxin is indicated, the patient should be desensitized; standard protocols for desensitization are published.<sup>27</sup>

Toxin-mediated complications are uncommon in cutaneous diphtheria, but have occurred. Use of antitoxin may be indicated in patients with extended, multiple pseudomembranous lesions.<sup>22</sup>

Although antimicrobial agents are of secondary importance in the treatment of diphtheria, they will hasten clearing of the organism and may result in less risk of transmission of diphtheria to others. Agents of choice are penicillin or erythromycin, which are highly active against *C. diphtheriae*. Until the patient can swallow easily, parenteral administration is recommended, with dosages of intramuscular procaine penicillin G (25,000–50,000 units/kg/day for children and 1.2 million units/day for adults in two divided doses) or parenteral erythromycin (40–50 mg/kg/day with a maximum dosage of 2 g/day). Once the patient can swallow easily, oral erythromycin in four divided doses or oral penicillin 125 to 250 mg four times a day can be substituted to complete the 14-day course of therapy.<sup>28</sup> In mild cases, oral therapy may be used for the complete course of treatment. Erythromycin resistance has been reported in areas where erythromycin has been used widely for treatment of cutaneous diphtheria; likewise, tetracycline and rifampin resistance have also been reported.<sup>29,30</sup>

Without antitoxin treatment, respiratory diphtheria is frequently fatal, with case-fatality rates of 30% to 50% reported. With introduction of diphtheria antitoxin for treatment of diphtheria, mortality has decreased to 5% to 10% in most series. In diphtheria, receipt of antitoxin within the first 2 to 3 days of illness is clearly associated with reduced mortality. Disease in vaccinated persons is usually mild.

## PREVENTION AND CONTROL

Vaccination of infants with diphtheria toxoid in combination with tetanus toxoid and whole-cell pertussis vaccines (DTP) in many countries of the world has resulted in dramatic reductions in diphtheria incidence globally. In developing countries, the highest priority for diphtheria prevention and control is to reach a high coverage rate for the primary series of three doses of DTP in infants. In endemic areas, infant immunization will protect young children from diphtheria, although it will not prevent continued circulation of the organism, and immunity of older children and adults will be maintained by re-exposure. Frequent skin infections due to *C. diphtheriae* are thought to contribute to maintenance of population immunity in countries where diphtheria is endemic.<sup>6</sup>

Effective childhood immunization programs do not result in eradication of the organism, but do result in reduced circulation; at that point, disease may be seen among adolescents and young adults—especially those who did not receive a primary series when the immunization program was just

beginning. Additional immunization strategies must be considered in the context of overall national health priorities, but additional doses of diphtheria toxoid at school entry are indicated if outbreaks occur among schoolchildren, and a dose at school leaving may be operationally the easiest to implement if disease is occurring among adolescents and young adults.<sup>6</sup>

Once a case is recognized, the following measures are recommended to limit further spread. Strict isolation should be maintained until elimination of the organism is demonstrated by negative cultures of two samples obtained at least 24 hours apart after completion of antimicrobial therapy. Close contacts (household members and other persons with a history of direct contact with the case-patient) should be identified and evaluated for signs and symptoms of diphtheria. As soon as nasopharyngeal and pharyngeal swabs are obtained for culture, antimicrobial prophylaxis should be administered regardless of prior vaccination status. Recommended regimens include a single dose of intramuscular benzathine penicillin G (600,000 units for children less than 6 years of age and 1.2 million units for persons older than 6 years of age) or a 7- to 10-day course of oral erythromycin (40 mg/kg/day for children and 1 g/day for adults). Although there is some evidence that erythromycin may be more effective at eradication of the carrier state than penicillin, a single dose of benzathine penicillin administered intramuscularly may be preferred if compliance is in doubt. Persons who continue to harbor the organism after treatment with either agent should receive an additional 10-day course of erythromycin and follow-up cultures should be obtained. Vaccination status of contacts should be assessed and, if indicated, vaccine administered. Surveillance of close contacts should be maintained for at least 7 days, but hospitalization in the absence of clinical illness is not indicated.<sup>28</sup> Reporting of cases of diphtheria to public health authorities is required by law in many countries.

For control of epidemic diphtheria in the former Soviet Union, the European Region of WHO recommended early diagnosis and proper management of diphtheria cases, rapid investigation and standard treatment of contacts, and rapidly increasing population immunity by attaining high coverage among children through routine vaccination—95% coverage with four doses of DTP in all districts—and administration of a single dose of age-appropriate formulation of diphtheria toxoid to the entire population. Additional doses were also recommended for certain adult age groups and a booster should be given every 10 years to adults, especially travelers to endemic areas. Although optimal control has not yet been achieved in all countries of the former Soviet Union, the effectiveness of this strategy for outbreak control is now well established.<sup>31,32</sup>

In the United States and many other developed countries, diphtheria toxoid is administered to children less than 7 years of age with tetanus toxoid and acellular pertussis vaccine (DTaP); DTaP may also be combined with other vaccines in combination vaccines that decrease the number of injections that need to be administered simultaneously. U.S. immunization authorities recommend that children receive DTaP at 2, 4, and 6 months of age, with booster doses at 15 to 18 months and 4 to 6 years. Adult formulation tetanus and diphtheria toxoids (Td) are recommended every 10 years, beginning at

age 11 to 12 years. Travelers to diphtheria-endemic areas are at risk of contracting diphtheria and should be age-appropriately immunized prior to travel.<sup>33</sup>

## Tuberculosis and Atypical Mycobacterial Infections

JOHN L. JOHNSON  
JERROLD J. ELLNER

### INTRODUCTION

Tuberculosis (TB) is a chronic necrotizing granulomatous disease caused by the acid-fast bacillus *Mycobacterium tuberculosis* or the closely related species *M. bovis* and *M. africanum*. It is spread primarily by inhalation of aerosolized infectious droplet nuclei from patients with active pulmonary TB. The lungs are the main portal of entry. The most common manifestation of TB in humans is pulmonary disease, but nearly all organ systems can be involved. The most frequent sites of extrapulmonary disease are the lymph nodes, pleura, and bones and joints.

TB occurs worldwide, but more than 95% of cases and 98% of deaths occur in developing countries. Miliary and meningeal TB in children and TB occurring in human immunodeficiency virus (HIV)-coinfected people are important causes of death in areas of high prevalence. *Mycobacterium bovis* is still a significant cause of human disease in developing countries unless infected and diseased cattle are identified and destroyed in skin test programs and milk is pasteurized.

### AGENT

*Mycobacterium tuberculosis* is a slender nonmotile bacillus approximately 2 to 4  $\mu\text{m}$  in length. It is an obligate aerobic organism and grows best in tissues with high ambient oxygen tensions, such as the apices of the lung or the renal cortex. The cell wall consists of a waxy coat containing mycolic acid and other complex lipopolysaccharides. This unique cell wall gives members of the genus *Mycobacterium* their characteristic acid-fast staining property. After staining with carbol fuchsin, mycobacteria are not decolorized by washing with acid alcohol. Mycobacteria take up other stains, such as Gram stain, poorly. *Mycobacterium tuberculosis* typically appears as a slender solid or beaded organism, and virulent strains are often aggregated in clumps in culture. The complete genome of a virulent laboratory strain of *M. tuberculosis* H37Rv was the first to be sequenced,<sup>1</sup> leading to new knowledge about the pathogenesis and virulence of tuberculosis and promising to accelerate

the identification of new targets for diagnostic testing, treatment, and vaccine development.

*Mycobacterium africanum* can be reliably distinguished from *M. tuberculosis* only by biochemical testing. The clinical features, drug susceptibility, and outcomes of *M. africanum* disease are similar to those of *M. tuberculosis*. The bovine tubercle bacillus, *M. bovis*, shares greater than 95% DNA homology with *M. tuberculosis* and causes disease in humans, cattle, deer, badgers, and other animals. Speciation can be performed only by specialized laboratories. Most strains are niacin positive, do not reduce nitrate, and are resistant to pyrazinamide.

Tuberculosis is predominantly spread by droplet nuclei that are generated during coughing and sneezing by people with active pulmonary TB. Direct transmission by heavily infected body secretions from fistulas and skin lesions occurs infrequently. Cutaneous TB from direct inoculation occurs rarely in pathologists ("prosector's wart") and laboratory workers. Fomites (eating utensils, clothing, and bedding) play no role in TB transmission among humans. Large droplet nuclei rapidly settle out of air currents or are removed by the mucociliary ladder in the upper airway and present little danger. Bacteria in small droplets are rapidly killed by drying and exposure to ultraviolet (UV) light. Tubercle bacilli in droplet nuclei measuring 1 to 5  $\mu\text{m}$  in diameter remain suspended in air for long periods, where they can be inhaled and reach the distal airspaces to establish a primary focus of infection. The number of bacilli needed to produce infection is low; infection in humans may occur when as few as one to five bacilli impact in a terminal alveolus.

The risk of infection is related to the duration and severity of exposure to infectious droplet nuclei. The length of exposure must generally be prolonged; brief casual exposures usually do not result in infection.<sup>2</sup> The density of infectious droplet nuclei in the air in proximity to an active TB case is related to the smear status of the index case (bacillary density), cough frequency, and the number of air exchanges (ventilation) in the area. Because up to 1000 to 10,000 acid-fast bacilli (AFB) per milliliter of sputum must be present for a positive AFB smear,<sup>3</sup> smear-positive people are the most important sources of transmission of TB in the community. Approximately 30% to 60% of people heavily exposed to smear-positive individuals with pulmonary TB become infected. For programmatic purposes, AFB smear-negative patients usually are considered to be noninfectious. In fact, they may account for up to 17% of new cases.<sup>4</sup> Crowded housing also leads to increased transmission of TB due to repeated and prolonged exposure and decreased air exchanges. Most transmission of TB occurs in household contacts—that is, people living in the same residence with an infectious smear-positive case. Intimate contact such as sharing a bed with a patient with TB poses the greatest risk.

### EPIDEMIOLOGY

TB is a major global health problem. Up to one-third of the world's population is infected with *M. tuberculosis*. The World Health Organization (WHO) estimates that 8 million new TB cases and 1.9 million deaths occurred in 2000 due to TB, making it the second leading cause of death due to an identified infectious pathogen worldwide, exceeded only by HIV/AIDS.<sup>5,6</sup> Most of the burden of TB falls on developing

countries: More than 95% of all TB cases and 98% of all deaths due to TB occur in developing countries, especially those in sub-Saharan Africa and Asia. Up to 7% of all deaths and 26% of preventable deaths in developing countries are due to TB.<sup>7,8</sup> TB predominantly affects young adults in their most productive years of life and has substantial impact on economic development.

Tuberculosis also is increasingly an urban problem. Two-thirds of the world's population will live in cities by 2025; many will live in crowded, substandard housing with poor ventilation in large cities in developing countries in Asia and Africa.

### **Tuberculosis and Human Immunodeficiency Virus Interactions**

HIV infection currently is the greatest risk factor known for the progression of latent *M. tuberculosis* infection to active TB and for the rapid progression of new infection to TB. Thirty to 40% of all new TB cases in many African countries occur in HIV-coinfected people, with rates as high as 60% to 70% in some eastern and southern African nations.<sup>5</sup> Increasing rates of HIV coinfection in countries such as Botswana have led to rapid increases in the incidence of TB despite the introduction of more effective TB treatment strategies using the Directly Observed Therapy, Short Course (DOTS) strategy.<sup>9</sup> In 2000, at least 11.4 million people were infected by HIV and *M. tuberculosis*; the majority live in Asia and sub-Saharan Africa. Globally, approximately 11% of all new TB cases—double the percentage in 1990—occur in HIV-infected people.<sup>5,10</sup>

The cumulative risk of developing active TB in HIV-infected people is markedly higher than the 5% to 10% lifetime risk in tuberculin skin test (TST)-positive HIV-noninfected people.<sup>11,12</sup> The reported risk of developing active TB in HIV-infected people is approximately 8% per year among TST-positive people.<sup>13–16</sup> Increasing TB cases among HIV-infected people also pose a threat to public health because TB can be spread to both HIV-infected and HIV-noninfected people in the community.

The clinical manifestations of TB in HIV-coinfected people are highly dependent on which infection (HIV or TB) occurs first and the degree of immunosuppression. In developing countries with a high prevalence of TB, many people become infected with *M. tuberculosis* during childhood and early adolescence. Most will not develop active TB after primary infection. People with latent TB infection who later become coinfecting with HIV have a subsequent 5% to 8% annual risk of developing reactivation TB. The risk depends on the severity of HIV-related immunosuppression. TB developing early after HIV infection when CD4 counts are high presents predominantly as pulmonary disease with typical clinical and radiographic manifestations. With advanced HIV-related immunosuppression, the presentation becomes more atypical (lower lobe noncavitating infiltrates and intrathoracic adenopathy) with an increase in extrapulmonary disease.

People who are infected with HIV and who then later become infected with *M. tuberculosis* frequently develop rapidly progressive primary TB. Active sputum smear-positive TB developed within 4 months in 37% of HIV-infected people exposed to two TB patients in a group home for HIV-infected people in San Francisco.<sup>17</sup> In a nosocomial TB outbreak in Italy, 8 of 18 HIV-infected patients exposed to a single sputum

smear-negative TB patient developed active TB, 7 within 60 days of diagnosis of the index case.<sup>18</sup> In areas with a high prevalence of TB, HIV-infected people successfully treated for TB also are at increased risk to develop recurrent TB due to reinfection. In a prospective study of South African mine workers, 62% of relapses in HIV-infected adults were due to reinfection compared to 6% in HIV-noninfected individuals.<sup>19</sup>

Despite good clinical and microbiologic responses to TB chemotherapy,<sup>20–24</sup> the development of active TB in HIV-infected people appears to be associated with shortened survival<sup>24,25</sup> due to enhanced cytokine expression and increased HIV replication.<sup>26</sup> TB is now the leading cause of death in HIV-infected people globally, especially in sub-Saharan Africa, where it has been found at postmortem examination in 40% to 54% of HIV-infected adults.<sup>27,28</sup> Globally, 13% of all deaths due to TB occur in HIV-infected people<sup>5</sup>; this proportion will likely continue to increase due to the increasing occurrence of HIV infection in populations already infected with *M. tuberculosis*.

### **Tuberculin Skin Test**

Tuberculin skin testing is widely used in epidemiologic surveys to assess the prevalence and estimate the annual rate of TB infection and in clinical practice to assess whether a person has been infected with *M. tuberculosis*. Many commercial purified protein derivative (PPD) antigens are available and are standardized by comparison with an international standard PPD-S in human subjects. Five tuberculin units (equivalent to 0.0001 mg of the international standard) is the dose widely used for tuberculin skin testing. Skin testing should be performed by intradermal injection (Mantoux method) of 5 tuberculin units of antigen in 0.1 mL, usually into the skin of the volar surface of the forearm. Correctly placed injections produce an immediate raised wheal. The test should be read as the number of millimeters of palpable induration present after 48 to 72 hours.

The operating characteristics of the test are dependent on the population tested, the amount of nonspecific cross-reactions (generally small reactions) due to exposure and infection with environmental mycobacteria, and the cut point used. Most people with reactions greater than 10 mm are infected with *M. tuberculosis*. A cut point of 5 mm is recommended when testing HIV-infected people. The presence of a positive tuberculin test indicates only prior infection with *M. tuberculosis* and not active disease. In fact, up to one-fourth of newly diagnosed patients with active pulmonary TB have negative tuberculin reactions.

False-negative PPD tests can be caused by protein-calorie malnutrition, other diseases such as sarcoidosis and HIV infection, intercurrent viral infections, and immunosuppressive drugs such as corticosteroids. False-positive reactions are often due to cross-reactions with environmental mycobacteria. The size of a previously positive tuberculin reaction may wane over time. Repeated testing of such a patient may result in the perception of new TST conversion suggesting recent infection. Two-step tuberculin tests in which PPD testing is repeated on people with a negative initial PPD skin test 1 week later can be used to identify this booster phenomenon. If the second PPD test is reactive, the positive test should be ascribed to boosting rather than to recent infection.

It is not possible to definitively distinguish between positive PPD skin reactions due to *M. tuberculosis* infection and

reactions due to previous bacille Calmette–Guérin (BCG) vaccination. Reactions due to BCG vaccination wane with time. The larger the reaction, the more likely it is due to *M. tuberculosis* infection. Routine BCG vaccination in infancy has little impact on the size of the TST reaction in adults; however, it may be a confounding factor in people revaccinated at school age or adolescence.<sup>29</sup>

Recent knowledge about the important role of T lymphocytes and interferon- $\gamma$  (IFN- $\gamma$ ) in tuberculosis has led to the development of in vitro diagnostic assays to detect tuberculous infection. QuantiFERON-TB is a new test based on antigen-specific stimulation of IFN- $\gamma$  release from mononuclear cells in a peripheral blood sample from a person being evaluated for latent TB infection.<sup>30,31</sup> Mycobacterial and control antigens are incubated with the blood sample overnight and the amount of IFN- $\gamma$  in the supernatant is measured. The use of mycobacterial antigens including early secreted antigen-6 (ESAT-6) and culture filtrate protein-10 that are found in MTB, but not in BCG or most other nontuberculous mycobacteria, enhances the specificity of this new test. This assay offers the advantages that it can be done in a single visit, there is little interobserver variability, and there are no boosted responses.

## DISEASE

### Risk Factors for Progression from Infection to Active Tuberculosis

Most people infected by *M. tuberculosis* do not develop active TB. In such people, infection is typically marked only by the development of a positive PPD skin test. Five percent to 10% of HIV-noninfected people develop active TB during their lifetime.<sup>11</sup> The risk is greatest in the first 2 years following infection and then declines. The risk of developing TB is associated with more intense exposure and is higher for people infected through contact with an index sputum smear-positive TB case.<sup>2</sup> The age at the time of TB infection is also important. People who become infected in infancy, adolescence, or old age are more likely to develop active TB.

The risk of developing progressive primary or reactivation TB is increased in immunocompromised people; the degree of risk varies with the underlying disease-impairing host defenses. The risk of developing TB among HIV-infected people was 79-fold greater than in HIV-noninfected people in one study<sup>13</sup> and may be up to 170-fold higher in patients with acquired immunodeficiency syndrome (AIDS).<sup>32</sup> People with silicosis, end-stage renal disease, certain malignancies such as head and neck cancers and lymphomas, poorly controlled diabetes mellitus, chronic malnutrition, rapid weight loss, chronic treatment with corticosteroids and other immunosuppressive drugs, and those who smoke tobacco are also at increased risk of developing TB, although the relative risk is much less than that of HIV-infected people. The duration and dose of corticosteroid use associated with an increased risk of TB are unknown; however, treatment for less than 3 or 4 weeks with doses of 15 mg of prednisone or less daily probably causes little increased risk.

### Primary Tuberculosis

TB infection is usually acquired by the inhalation of droplet nuclei containing viable tubercle bacilli that are phagocytosed

by alveolar macrophages to establish a primary nidus of infection. In the nonimmune host, the bacilli multiply intracellularly, kill the cell, and then spread to the draining hilar lymph nodes or to the bloodstream via the thoracic duct. Most primary infections are asymptomatic, but some people develop fever, nonproductive cough, dyspnea, and, occasionally, erythema nodosum. Symptoms are more common in children than adults. Crepitations from alveolar consolidation and focal wheezes due to bronchial compression by enlarged intrathoracic lymph nodes may be present. Lesions demonstrable on chest film include small patchy alveolar infiltrates in the middle and lower lung fields, often with unilateral hilar adenopathy. Bronchial compression by enlarged nodes may produce upper or middle lobe collapse. Small transient pleural effusions occur in 10% of patients.

The vast majority of immunocompetent people develop an effective immune response against TB and contain their primary infection, leaving only small calcified parenchymal scars (Ghon complex), usually in the middle and lower lung fields. If the corresponding draining hilar lymph node is visible, the radiographic lesion is termed a Ranke complex (Fig. 36-1A). Small scars due to arrested lesions from seeding of tubercle bacilli to the apical regions of the lung at the time of primary infection are known as Simon's foci (Fig. 36-1B). In many people, however, residua of the primary focus are undetectable on subsequent chest x-ray films.

Following primary infection, immunocompetent people develop specific acquired resistance to reinfection. Although incompletely understood, the protective immune mechanisms appear to include T lymphocyte-dependent activation of macrophages to destroy tubercle bacilli. Specific acquired resistance is long-lasting, possibly due to repeated primary but clinically latent foci of infection. Conditions such as HIV infection associated with immunosuppression may lead to lowered resistance to exogenous reinfection.<sup>19</sup> Reinfection is most likely to contribute substantially to new cases of TB in areas of high prevalence and transmission.

### Progressive Primary Tuberculosis

People who fail to develop specific acquired immune responses following primary TB infection may develop progressive primary TB. This form of disease is most common in young children, the immunocompromised, and the elderly. Miliary or meningeal disease may result after widespread hematogenous dissemination of tubercle bacilli. The clinical presentation is frequently cryptic with nonspecific symptoms such as malaise and fatigue or fever of unknown origin.<sup>33</sup> Progressive primary disease in young adults presents with fever, productive cough, night sweats, weight loss, and upper lobe cavitory lesions, which can be reliably distinguished from reactivation TB only when recent PPD skin test conversion has been documented.<sup>34</sup>

### Reactivation (Postprimary Tuberculosis)

Although acquired immune responses are crucial to mycobacterial killing and the prevention of progressive pulmonary or disseminated disease after primary infection, they do not totally eradicate all viable tubercle bacilli. Low numbers of dormant, slowly metabolizing organisms persist in small,

A

B

walled-off fibrocaceous lesions in the lung and other organs seeded during the initial bacilleemia. These foci may “break down” years to decades later in the presence of waning immunity to produce active local or disseminated disease.

The lungs are the most common site of reactivation TB. Chronic cough productive of purulent sputum of greater than 2 or 3 weeks' duration, night sweats, weight loss, and anorexia are the most frequent complaints. From 40% to 60% of patients are afebrile at presentation. The onset of symptoms usually is insidious. Approximately one-fifth of patients with reactivation TB have no chest symptoms and the diagnosis is detected on a routine chest radiograph.<sup>35</sup>

Hemoptysis may occur and varies from blood-streaked sputum due to endobronchial lesions to massive, sometimes fatal, hemoptysis in patients with far-advanced cavitory disease. Large subpleural lesions may cause adjacent pleural inflammation and pleuritic chest pain. TB is characterized by brisk local inflammation and thrombosis of small pulmonary vessels contiguous to active lesions resulting in the loss of perfusion to poorly ventilated, diseased lung areas. This may explain the relatively low frequency of dyspnea in active TB until the disease is very extensive. Rarely, large lesions or cavities rupture into the pleural space producing a pneumothorax and chest pain and sudden dyspnea.

Signs of consolidation, coarse or fine crepitations and bronchial breath sounds, are present on auscultation over affected lung zones. In some instances, crepitations may be heard only after the patient has been instructed to take several deep breaths, cough vigorously, and take further deep breaths (“posttussive rales”). Low-pitched amphoric breath sounds (named for their resemblance to the sound produced by blowing across the opening of a wide-mouthed jug) may be heard over large cavities. Dullness to percussion and decreased tactile and vocal fremitus at the lung bases indicate the presence of concomitant pleural effusion or thickening.

The chest radiographic findings in reactivation TB are varied.<sup>35,36</sup> In many cases, they are more extensive than suggested by physical examination of the thorax. Lesions are characteristically localized to the apical and posterior segments of the upper lobes (Fig. 36-2) and the superior (dorsal) segment of the lower lobes, although other areas may be involved less frequently. The reasons underlying the predilection for reactivation TB to occur in the lung apices are not known with certainty but have been conjectured to be due to higher ambient oxygen tensions favoring mycobacterial growth or to decreased lymphatic clearance from these areas. Intrathoracic lymphadenopathy is uncommon in reactivation TB. The radiographic lesions are usually asymmetrical and

A

B

**FIGURE 36-2** Posteroanterior (A) and left lateral (B) chest x-ray showing typical reactivation (post-primary) tuberculosis in the adult. Bilateral upper lobe fibrocavitary disease affecting predominantly the apical and posterior segments of the right upper lobe.

begin as areas of consolidation with focal infiltrates. Local inflammation and host responses lead to caseation and pulmonary necrosis. If these areas liquefy and rupture into a bronchus, cavities result. Early cavities are thin walled and have surrounding infiltrates, and only approximately 10% have visible air–fluid levels.

Caseous necrosis and cavitation are critical events in the natural history of TB because local conditions in the cavity are conducive to rapid bacillary growth. TB can then be spread to other areas of the lung by spillage of caseous material from cavities into the airways with subsequent bronchial and aerogenous spread. The upper airways may become involved, resulting in tuberculous laryngitis and otitis media.

Infectious sputum may be swallowed, leading to tuberculous enteritis or peritonitis.

Parenchymal lesions heal by fibrosis, leaving round or linear scars. Small cavities may be obliterated by fibrosis and contraction; however, large thick-walled cavities often persist. Such lesions, even when sterilized by effective anti-TB chemotherapy, may later become colonized by aspergillus or other, atypical mycobacteria. Erosion and rupture of small nonthrombosed pulmonary arteries in the walls of chronic tuberculous cavities (Rasmussen's aneurysm) can produce massive life-threatening hemoptysis. Late hemoptysis may also be due to fungal infection of residual cavities (mycetoma), bronchiectasis, or erosion of old calcified nodes into a central bronchus, and it does not necessarily imply that active TB disease is present.

Reactivation TB also presents with lower lobe disease ranging from dense, poorly resolving lobar or segmental infiltrates to atelectasis or large mass lesions or cavities.<sup>37,38</sup> The last-named are often mistaken for lung cancers or putrid lung abscesses. Lower lobe TB may be more common in diabetic patients and immunosuppressed hosts. The diagnosis often is delayed because of failure to consider TB, especially when such patients fail to respond to empirical treatment for pyogenic pneumonia or mixed aerobic–anaerobic lung abscess. Rarely, patients with reactivation TB present with normal chest x-rays and positive acid-fast bacilli (AFB) smears and cultures resulting from endobronchial lesions or old tuberculous nodes that have eroded and are discharging into the bronchial tree.

For detailed information, the reader is referred to several excellent reviews of the radiographic manifestations of TB in normal and immunocompromised hosts.<sup>36,39–41</sup>

### Pediatric Tuberculosis

Children usually acquire tuberculous infection from repetitive close contact with an infectious, typically sputum smear–positive, adult. Most infections are contracted from someone living in the same household. The younger the child, the more likely it is that he or she has been infected by a household member.

Malaise, fever, failure to thrive, and erythema nodosum may occur with progressive primary disease. Contrary to the usual presentation in adults with productive cough and chest pain, cough is an infrequent presenting complaint in children with TB except for those with endobronchial disease. Because pulmonary necrosis and cavitation are less frequent in children, the bacillary burden is usually lower; therefore, children are less likely to be sputum AFB smear positive and a source of transmission to others. With regard to clinical symptoms, radiographic signs, and sputum positivity, children's cases begin to resemble adult cases of TB at approximately 15 years of age.

The diagnosis of TB in children is problematic.<sup>42–44</sup> Children often do not produce sputum for examination. Gastric lavage can be performed to obtain swallowed sputum, but the process is time-consuming and uncomfortable for young children and has a low sensitivity of approximately 50%. In most instances, a presumptive diagnosis is made and anti-TB treatment is initiated based on the constellation of a positive PPD reaction in a child with compatible chest film findings and exposure to a known infectious case or residence

in a high-prevalence area. This conservative approach is warranted because children are at high risk of progressive TB and miliary and meningeal disease.

### Pulmonary Tuberculosis in Immunocompromised Patients

Patients who are mildly immunocompromised may present with typical reactivation TB with cough, sputum production, malaise, and weight loss and a radiographic picture of apical fibrocavitary disease.

Severely immunocompromised patients are at high risk of developing progressive primary TB if recently infected and for reactivation of latent TB infection. These patients may present with disseminated disease or overwhelming pneumonia and the adult respiratory distress syndrome. The spectrum of chest radiographic lesions ranges from abnormalities comparable to those in primary TB to diffuse pulmonary infiltrates, often without cavitation, and miliary disease.<sup>39</sup> The absence of cavitation and the presence of diffuse or lower lung field location of the infiltrates often results in delayed diagnosis and treatment and likely contributes to the high mortality of TB in immunocompromised patients.

### Tuberculosis in People with Human Immunodeficiency Virus Infection

*Mycobacterium tuberculosis* is a highly virulent human pathogen and produces disease throughout the course of HIV infection. During the early stages of HIV infection when host defenses are less impaired, TB usually presents with clinical and radiographic features consistent with typical reactivation-type fibrocavitary disease.<sup>45,46</sup>

As HIV infection progresses, the clinical and radiographic presentation of TB becomes more atypical. With progressive immunosuppression, the TST may revert to negative. TB in severely immunosuppressed HIV-infected people is characterized by an increase in disseminated and extrapulmonary forms of disease. In one representative study of patients with advanced AIDS and TB, 38% of patients had pulmonary TB only, 30% had extrapulmonary disease only, and 32% had both pulmonary and extrapulmonary disease.<sup>21</sup> Widespread TB was present in 54% of adult patients dying with AIDS in an autopsy series from Côte d'Ivoire and was thought to be the primary cause of death in 32%,<sup>28</sup> but it was much less common (2%) in HIV-infected children dying at the same institution.<sup>47</sup>

Pulmonary disease is present in 65% to 93% of HIV-infected patients with TB.<sup>20,21,48–53</sup> Chest films often show lower lung zone or diffuse infiltrates, mediastinal or hilar lymphadenopathy, pleural involvement, and a lower frequency of cavitory disease (Fig. 36-3). Five percent to 8% of HIV-infected people with proven TB have a normal chest film.<sup>54,55</sup> Unlike TB in HIV-noninfected patients, where positive blood cultures occur in fewer than 5% of patients, mycobacterial blood cultures are positive in 26% to 42% of patients with AIDS and TB,<sup>56–58</sup> including one-third of patients with occult disseminated disease.

The yield of sputum microscopy for the diagnosis of TB also may be lower in HIV-infected people, making diagnosis more difficult in programs where microscopy is the only

A

B

**FIGURE 36-3** Atypical presentations of pulmonary tuberculosis in HIV-infected adults. A, Right midlung field infiltrate with ipsilateral hilar adenopathy and absence of cavitation resembling primary tuberculosis. B, Dense mid and lower lung field infiltrates.

available diagnostic test. Studies from developing and industrialized countries suggest that HIV-infected TB patients have smaller numbers of bacilli in the sputum and a lower frequency of positive sputum AFB smears (45%–67%) than HIV-noninfected people.<sup>59–63</sup> Sputum cultures are positive in 62% to 93% of cases, comparable to HIV-noninfected patients.<sup>21,61,64</sup> The increased number of smear- and culture-negative cases probably reflects the contribution of noncavitary cases.

The histopathologic findings in the lungs of HIV-infected patients with active TB are characterized by higher bacillary burdens and poorly organized local granulomatous inflammation compared with HIV-noninfected TB patients. Greater numbers of AFB and more poorly formed granulomas are present in patients with more severe degrees of immunosuppression and lower CD4 lymphocyte counts.<sup>65</sup> Despite the higher tissue burdens of tubercle bacilli in HIV-infected TB patients, epidemiologic studies from both developing and industrialized countries have shown that HIV-infected patients are comparably or less infectious than HIV-noninfected patients.<sup>66–71</sup>

### Extrapulmonary Tuberculosis

Tuberculosis can affect nearly all organ systems. Most cases of extrapulmonary disease represent reactivation TB due to the breakdown of previously dormant foci established during the primary infection. A few forms of extrapulmonary disease, such as tuberculous pleurisy and phlyctenular conjunctivitis, represent hypersensitivity reactions to mycobacterial proteins and occur following primary infection. Approximately 20% of HIV-noninfected patients with TB have extrapulmonary disease.

In developing countries with a high prevalence of TB infection, extrapulmonary TB frequently occurs in children and young adults. This is in contrast to industrialized nations, where extrapulmonary TB is more frequent in the elderly, presumably due to reactivation of TB in the setting of declining immunity related to aging. The frequency of disseminated TB and some forms of extrapulmonary TB, such as tuberculous meningitis, is clearly increased among HIV-infected people.

Several points about extrapulmonary tuberculosis require emphasis. Diagnosis is frequently more difficult than that for pulmonary disease. Miliary, meningeal, and abdominal TB frequently present with nonlocalizing systemic symptoms, such as fever and failure to thrive. Cutaneous anergy to PPD occurs in 35% to 50% of patients with these forms of TB. One-fourth to one-third of people with HIV infection with extrapulmonary TB lack clinical and radiographic evidence of active or remote pulmonary TB. Therefore, normal chest films and negative PPD skin tests cannot be used definitively to exclude the diagnosis of TB. Common forms of extrapulmonary TB are discussed in the following sections.

### Tuberculous Pleurisy

Tuberculosis can involve the pleural space by direct extension, hematogenous seeding, or, most frequently, rupture of a subpleural caseous focus into the pleural space. Tuberculous pleurisy with effusion usually develops 3 to 6 months after primary infection.<sup>72</sup> Five to 20% of HIV-noninfected adults have pleural effusions at the time of diagnosis with intrathoracic TB, and TB is the most common cause of pleural effusions in many developing countries.<sup>73,74</sup>

Relatively few bacilli are present in the pleural space so that the pleuritis has been attributed to an *in situ* delayed-type hypersensitivity (DTH) response to mycobacterial proteins. Exudative pleural effusions have been induced experimentally in tuberculin-sensitized guinea pigs by injecting tuberculin into the pleural space.<sup>75</sup> PPD-specific T lymphocytes are present in the pleural fluid in greater numbers than in the peripheral

blood in patients with TB pleurisy.<sup>76</sup> These lymphocytes are predominantly T helper cells. The marked local inflammation is mediated by the release of high levels of several cytokines, including IFN- $\gamma$ , interleukin (IL-2), and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), by activated PPD-specific T lymphocytes and macrophages.<sup>77–81</sup>

Tuberculous pleurisy typically presents with the abrupt onset of fever, cough, and pleuritic chest pain, but it may have a more chronic course with fever, weight loss, and malaise. In one study, two-thirds of patients had symptoms for less than 1 month and one-third were ill for less than 1 week.<sup>82</sup> Chest films show a small to moderate-sized pleural effusion with visible parenchymal disease in one-third to one-half of cases. When unilateral, the effusions are more frequently right-sided (57%).<sup>83</sup> Approximately 10% have bilateral effusions.<sup>83,84</sup> Initial PPD skin tests are negative in one-third of cases but become reactive in nearly all patients if retested 6 to 8 weeks later.<sup>83</sup> Tuberculin anergy may seem paradoxical given the vigorous DTH response in the pleural space. Mononuclear suppressor cells have been detected in the circulation, but not the pleural fluid, of PPD anergic patients with tuberculous pleurisy.<sup>85,86</sup>

The pleural effusion is usually an exudate containing greater than 50% lymphocytes. Neutrophils may predominate in the first few weeks after the development of the effusion. Owing to the chronic pleural inflammation, it is unusual to find more than 5% mesothelial cells.<sup>87</sup> Low pleural fluid glucose is present in only approximately 20% of cases<sup>83</sup> but is an important diagnostic clue when present because the differential diagnosis of low pleural fluid glucose (<60 mg/dL) is limited, with few exceptions, to four conditions: malignancy, empyema, rheumatoid arthritis, and TB. Other ancillary tests useful in the diagnosis of tuberculous pleurisy include measurement of pleural fluid adenosine deaminase and IFN- $\gamma$ .<sup>88</sup>

Patients with suspected tuberculous pleurisy should undergo PPD skin testing and examination of the sputum and pleural fluid. Many patients with minimal parenchymal disease will have negative sputum smears due to the low bacillary burden. Sputum and gastric aspirate AFB smears are positive in less than one-third of patients.<sup>83</sup> AFB smears of pleural fluid also have a low diagnostic yield and mycobacterial cultures are positive in less than 25%.<sup>83,89</sup> Closed pleural biopsy with the Abrams' or Cope's needle is a very useful diagnostic technique. The presence of granulomas in pleural tissue, even in the absence of AFB or caseation, is highly suggestive of TB. A single pleural biopsy will demonstrate granulomas in approximately 60% of cases.<sup>90</sup> If multiple biopsy specimens are examined, the diagnostic yield increases to approximately 90%. Portions of the biopsy material should be submitted for histologic evaluation and special stains and other portions should be cultured. AFBs are seen in tissue sections in 5% to 18% of patients.<sup>89,90</sup> Using the combination of pleural biopsy histology and cultures, 85% to 95% of cases can be diagnosed.<sup>89,90</sup> Pleural biopsy cultures may still be positive up to several weeks after patients have been started on empirical anti-TB chemotherapy.

Pleural TB is frequent in HIV-infected patients, and pleural involvement has been reported in 28% to 38% of HIV-infected patients with TB.<sup>57,73</sup> The size of the effusions is similar to that of HIV-noninfected patients, although the duration of symptoms may be longer.<sup>91</sup> The diagnostic yield on pleural biopsy is also similar to that of HIV-negative patients; however,

pleural fluid cultures are significantly more likely to be positive in HIV-positive patients.<sup>91</sup> Inoculation of liquid as well as solid culture media enhances diagnosis.

In HIV-noninfected persons, tuberculous pleurisy is generally a self-limited condition with spontaneous resolution of the effusion even without specific anti-TB treatment. Unfortunately, 41% to 65% of these patients will later develop active TB, the majority within the first 3 years after the episode of pleurisy.<sup>92,93</sup> Tuberculous pleurisy responds extremely well to modern chemotherapy regimens. Isoniazid (INH) and rifampicin given daily for 9 months, or daily for 1 month followed by twice-weekly treatment for 5 or 8 months, cures more than 98% of patients.<sup>94,95</sup> Six-month short-course regimens including pyrazinamide are also highly effective. If the clinical suspicion for TB is high and pleural biopsy is unavailable or the biopsy histology and special stains are negative, another reasonable option is empirical treatment with specific anti-TB chemotherapy with repeat PPD skin testing and reevaluation in 4 to 6 weeks. Repeated thoracenteses are unnecessary. Intrapleural corticosteroids are of little value. A tapering course of adjunctive oral corticosteroids (prednisolone, 0.75 mg/kg/day) given during the first 2 or 3 months of anti-TB treatment was shown in one placebo-controlled study to increase the rate of resolution of symptoms and pleural fluid resorption but did not alter the extent of residual pleural thickening.<sup>96</sup> Corticosteroids probably are of marginal benefit in patients with small effusions and mild symptoms.

Large necrotic tuberculous foci or cavities occasionally rupture into the pleural space to produce a true tuberculous empyema. The pleural fluid is thick and cloudy with a high density of bacilli. An etiologic diagnosis usually can be established quickly by simple microscopy and culture of the pleural fluid. Tuberculous empyemas are usually associated with far-advanced cavitory disease. Treatment is difficult, may need to be prolonged, and should be given in conjunction with a chest consultant.<sup>97</sup> Drainage or decortication is often required. Secondary complications include extension through the chest wall producing chest wall abscesses and draining fistulas.

### Tuberculous Lymphadenitis

Lymphadenitis is the most common extrapulmonary manifestation of TB seen in developing countries. Although less frequent in developed nations, it is a significant problem in immigrants from high-prevalence countries in Asia and Africa. *Mycobacterium tuberculosis* is the most common cause of mycobacterial lymphadenitis worldwide. In developed nations with a low prevalence of TB, atypical mycobacteria, including *Mycobacterium avium-intracellulare* complex (MAC) and *Mycobacterium scrofulaceum*, are frequent isolates in pediatric cases.<sup>98</sup> Lymphadenitis may be a complication of primary infection, reactivation disease, or contiguous spread. It is more common in young children and women and may be more frequent among Asians and Pacific islanders.<sup>99</sup> Stigmas of active or remote pulmonary disease were present on chest radiographs in 39% of cases in one large series from Hong Kong.<sup>100</sup>

The cervical lymph nodes are most commonly involved; this form of disease is known as scrofula. The affected nodes characteristically are nontender and cause little pain. Tuberculous lymphadenitis is more likely to involve nodes in the supraclavicular and posterior fossae. Lymphadenitis due

to atypical mycobacteria is more likely to be present with disease in the submandibular and high anterior cervical lymph node groups.<sup>101</sup> The nodes are firm on palpation initially but may become matted and fluctuant as they become necrotic. Draining sinuses form frequently. Systemic symptoms such as fever, weight loss, and failure to thrive are common. Definitive diagnosis requires recovery of the organism on smears and cultures of aspirated material, draining pus, or lymph node biopsy material. The diagnostic yields, from AFB smears and culture of lymph node biopsies, were 56% and 69%, respectively, in one large study from Finland.<sup>102</sup> In hospitals where cytopathology is available, fine- or wide-needle aspiration cytology with AFB and hematoxylin and eosin (H&E) staining and mycobacterial culture is another useful diagnostic option.<sup>103,104</sup> AFB or caseation was seen in 75% of simple lymph node aspirates done for suspected tuberculous lymphadenitis at a teaching hospital in Zambia; 85% of these patients were HIV seropositive.<sup>104</sup>

Six- to 12-month short-course chemotherapy regimens including isoniazid and rifampicin (plus pyrazinamide for the first 2 months) are the mainstays of therapy. New enlarged nodes may appear and previously swollen lymph nodes may persist or enlarge slightly during or after chemotherapy; this is not a sign of treatment failure and such patients may be carefully followed.<sup>105</sup>

Routine surgical excision or aspiration confers no benefit or disadvantage and should be avoided.<sup>105</sup> Surgical management (total excision of involved nodes) should be reserved for diagnostic biopsy when necessary and for complications such as persistent draining sinuses and compromise of vital contiguous structures.

### Bone and Joint Tuberculosis

Skeletal TB affects mainly large weight-bearing joints (Table 36-1). Most cases involving synovial joints present with monarticular arthritis; however, spinal disease may occur at multiple levels. In cases of spondylitis, the most common sites are the lower thoracic and lumbar spine (48%–67% of cases).<sup>106</sup> Tuberculous osteomyelitis usually involves the metaphyseal regions of bones where the blood supply is greatest.

Most skeletal TB in infants and children is associated with progressive primary TB, whereas in older children and adults it usually results from reactivation of a previous hematogenously seeded focus<sup>107</sup> or by hematogenous seeding after breakdown of a long-latent focus in the kidney, lymph nodes, or other organs.<sup>106</sup> Spread from contiguous lymphatic structures (e.g., from the kidney or parietal pleura to para-aortic lymph nodes and then to the lumbar spine) may be important in the pathogenesis of some cases of tuberculous spondylitis.

**Table 36-1 Joints Involved with Skeletal Tuberculosis**

Affected Joint	Percentage of Cases
Spine	50
Hip	15
Knee	15
Wrist, ankle, others	20

TB affecting synovial joints produces a combination of arthritis and osteomyelitis. The main complaint is usually the insidious onset of pain and swelling in the affected joint. A history of trauma to the affected joint preceded the onset of tuberculous arthritis in one-fourth of patients in one study.<sup>107</sup>

In tuberculous spondylitis, the principal symptom is local or radicular pain (10%–30% of cases). Symptoms of spinal cord compression are more common with cervical spondylitis because the spinal canal is narrower at this level. Neurologic deficits tend to be symmetrical and slowly progressive over weeks to months, in contrast to the asymmetrical and rapidly evolving symptoms of neoplastic spinal cord compression. Spinal cord compression can occur due to extrinsic compression by caseous material, necrotic bone, vertebral subluxation, or direct tuberculous inflammation of the dura mater and meninges.<sup>108</sup> Lower extremity weakness, easy fatigability, loss of bowel and bladder control, and fever may occur.

Tuberculous spondylitis usually affects the vertebral body more than the posterior spinal elements (Fig. 36-4). Multiple vertebral levels may be involved. The initial site of disease is usually the subchondral region of the anterior portion of the vertebral body with preservation of the joint space. Proliferation of granulation tissue, pannus formation, and caseous necrosis then occur. Local disease may progress to involve the disk space and adjacent vertebrae. Collapse of the vertebral body may result in kyphosis or severe gibbus deformities. Necrotic debris tracks outward, limited by ligamentous and fascial planes. In the spine, the caseous material is limited anteriorly by the thick anterior spinous ligament and thus tends to bulge laterally, producing the typical fusiform appearance of the paraspinal (Pott's) abscess. Pus may dissect along other planes resulting in extrapleural, posterior cervical, retropharyngeal, and psoas abscesses.

**FIGURE 36-4** Tuberculous spondylitis. Lytic lesion involving the anterior and inferior aspect of the L3 vertebra and the posterior and superior aspects of the L4 vertebra with early sparing of the disk space.

### Box 36-1 Radiographic Features of Tuberculous Spondylitis

- Multiple levels of involvement
- Narrowing and destruction of the intervertebral space
- Destruction of both adjacent vertebral bodies
- Collapse (anterior wedging) of the vertebral bodies
- Paraspinal “cold” abscess formation–fusiform mass
- Kyphosis/gibbus deformity

The differential diagnosis includes other infectious and neoplastic spondylitides. Radiographic findings may be helpful (Box 36-1) but are nonspecific. Sparing of the disk space and destruction of the vertebral pedicles suggest spinal metastatic disease rather than tuberculous spondylitis.

The absence of pulmonary disease does not exclude the diagnosis of osseous TB. Fifty percent of patients with skeletal TB had normal chest films in one large series.<sup>109</sup> Positive TSTs occur in 77% to 100%. In the absence of concomitant pulmonary disease to obtain clinical specimens for diagnosis, biopsy of the affected bone with culture and histologic examination are usually necessary for definitive diagnosis. Aspirate or biopsy material is positive for tuberculosis in 50% to 71% of cases.<sup>109,110</sup> In cases with joint involvement, simple aspiration with AFB smear and culture should be the initial diagnostic procedure. AFB smears and cultures of joint fluid are positive in 25% and 60% to 94% of cases, respectively.<sup>107–111</sup> Synovial biopsy has a higher yield and is valuable when simple aspiration is nondiagnostic and the diagnosis remains obscure.

Several well-done controlled clinical trials by the British Medical Research Council demonstrated that most patients do well with prolonged (12–24 months) chemotherapy with isoniazid- and rifampicin-containing regimens. Prolonged bed rest, plaster casts, and routine surgical debridement added little or no additional benefit.<sup>112–115</sup> Spinal surgery is not indicated for the majority of patients. Severe neurologic deficits at the time of presentation, severe spinal instability, deterioration in neurologic status, and failure of neurologic signs to improve after several months of chemotherapy are indications for surgical treatment. Progression of disease should be assessed on clinical and neurologic as well as radiographic grounds. Modern short-course regimens including isoniazid, rifampicin, ethambutol, and pyrazinamide may be utilized. The duration of treatment required is controversial and should be individualized based on the patient's response to therapy. Many authorities recommend at least 12 months of therapy.

### Miliary Tuberculosis

The term *miliary tuberculosis* is used to describe disseminated TB resulting from hematogenous spread associated with characteristic lesions on chest radiography. Miliary lesions are diffuse 1- or 2-mm rounded opacities scattered throughout all lung fields and are named for their resemblance to millet seeds. Early lesions may be indistinct and easily missed (Fig. 36-5A). Advanced lesions may coalesce and appear as larger rounded lesions that occasionally cavitate (Fig. 36-5B). In developing countries with a high prevalence of TB, most

A

B

**FIGURE 36-5** A, Early miliary tuberculosis. Diffuse 1- or 2-mm rounded opacities involve all lung fields. B, Coalescence of smaller lesions in advanced miliary disease.

cases occur following primary infection. In industrialized countries, the majority of cases arise from breakdown and hematogenous seeding from old latent foci in the lung or other organs. Pathologically, the pulmonary lesions consist of aggregates of macrophages and lymphocytes in granulomas with or without caseous necrosis. In severely immunocompromised patients, such as patients with advanced AIDS, little tissue inflammation may be present and many bacilli may be visible.

Systemic symptoms predominate in patients with miliary TB despite the numerous pulmonary lesions. The chest is generally clear to auscultation. A minority have lymphadenopathy or hepatosplenomegaly. Choroidal tubercles, which are raised white-yellow plaques visible in the choroid on fundoscopic examination, are pathognomonic but occur in fewer than 15% of cases. Fever, weight loss, and failure to thrive are frequent, and miliary TB may be a cause of fever of unknown origin in the elderly.<sup>33</sup> Hematologic abnormalities ranging from leukopenia to leukemoid reactions occur in 10% of cases.<sup>116</sup> Patients may present with headache, confusion, personality change, and focal neurologic deficits due to concomitant central nervous system (CNS) involvement with tuberculous meningitis.

The diagnosis of miliary TB is usually straightforward when typical radiographic lesions are present. The PPD skin test is positive in only 52% to 72% of cases.<sup>117–120</sup> Patients with neurologic symptoms and signs should undergo lumbar puncture and cerebrospinal fluid (CSF) examination. Hyponatremia may be a clue to the syndrome of inappropriate secretion of antidiuretic hormone due to CNS disease. The diagnostic yields of sputum AFB smears and culture, urine and gastric aspirate culture, and tissue biopsies in patients with miliary TB are listed in Table 36-2.

Routine mycobacterial cultures may take 3 or more weeks to become positive. In urgent situations, when available, fiberoptic bronchoscopy with transbronchial lung biopsy has a diagnostic yield of 75% to 100%.<sup>118,124,125</sup> When classic necrotizing granulomas are present, a presumptive diagnosis can be reached quickly. When sputum examination is unrevealing, other tissue sites may be biopsied. Bone marrow aspiration and biopsy with smear and culture should be strongly considered in patients with hematologic abnormalities. Liver and lymph node biopsies also have high diagnostic yields. Treatment with the standard short-course regimens described later is recommended for cases of miliary TB.

**Table 36-2** Yield of Diagnostic Studies in Miliary Tuberculosis (Percentage with Positive Histology or Culture)

## Tuberculous Meningitis

TB involves the CNS in three ways. Tuberculomas are parenchymal mass lesions that produce focal symptoms by acting as space-occupying lesions. Tuberculous spondylitis can result in spinal cord compression or radiculopathy. The most frequent form of CNS TB is tuberculous meningitis. Tuberculous meningitis is the most life-threatening form of extrapulmonary TB and was uniformly fatal before the advent of antituberculous chemotherapy. It is still a leading cause of death and chronic disability in infants and children with TB.<sup>126</sup>

Unlike areas of the developing world with a high prevalence of TB where the infant or child develops tuberculous meningitis in the setting of progressive primary infection or miliary disease, in more developed nations tuberculous meningitis is more frequently seen in adults and the elderly in association with reactivation TB. The HIV pandemic has also been associated with increased case rates of CNS TB. Tuberculous meningitis occurs five times more frequently in HIV-infected people than those who are HIV seronegative.<sup>127</sup> Five percent to 10% of HIV-infected patients with TB have CNS involvement, predominantly as meningitis.<sup>21,127–129</sup> Tuberculous meningitis resembles many other forms of chronic meningitis. It occurs without other evidence of extracranial TB in a significant minority of cases, further increasing difficulties in diagnosis.

Tuberculous meningitis usually results from the rupture of a subependymal tuberculous focus into the CSF provoking a brisk local inflammatory and immunologic response.<sup>130,131</sup> The severe inflammatory responses in the subarachnoid space cause most of the symptoms and ultimate morbidity of tuberculous meningitis. Pathologic lesions include (1) a thick gelatinous basilar exudate capable of entrapping cranial nerves and blood vessels and blocking normal CSF resorptive pathways; (2) a severe arteriolitis and perivasculitis with subsequent endarteritis and thrombosis of nutrient vessels to the brain parenchyma, resulting in ischemia and infarction; and (3) severe comorbidity due to debility and secondary infection.

Adults may develop tuberculous meningitis in the setting of progressive primary disease or miliary TB similar to children. However, they may also develop it due to late meningeal seeding and subependymal tubercle formation from bacilli spread systemically from the breakdown of small cryptic smoldering or previously dormant renal and osseous foci.<sup>130</sup> Most cases have other clinical or radiographic stigmas of TB in other extracranial sites, but a few have no other apparent evidence of TB outside of the CNS.

Common clinical manifestations at the time of presentation for medical attention include headache, fever, irritability, and, in children, episodes of protracted vomiting. Fever is present in 47% to 100% of cases,<sup>132,133</sup> and meningismus is present in 57% to 90% of cases<sup>134,135</sup>; decreased level of consciousness, papilledema, and cranial nerve palsies (most commonly of the sixth cranial nerve, followed by palsies of the third, fourth, and seventh cranial nerves) are seen less frequently. The clinical presentation of tuberculous meningitis is similar in HIV-positive and -negative people.<sup>127,136</sup>

In adults, the presentation of tuberculous meningitis is similar to many other forms of chronic meningitis, with fever, meningismus, headache, and an abnormal level of consciousness.<sup>123</sup> The combination of leptomeningeal signs, especially new or evolving cranial nerve palsies, a chest film picture consistent

with TB, and a CSF profile of hypoglycorrhachia with lymphocytic pleocytosis should suggest the diagnosis.

The duration of symptoms prior to hospital admission varies from a few days to 6 months. Initial TSTs were positive in 31% to 61% of adult<sup>137,138</sup> and 50% to 96% of pediatric cases.<sup>126,139</sup> Sputum smears and cultures or gastric aspirate cultures were positive in 14% to 51% of cases.<sup>134,140</sup> The chest radiograph is helpful diagnostically: 44% to 88% of all adult and pediatric patients have radiographic abnormalities compatible with pulmonary TB.<sup>135,141</sup> Approximately 20% will have a miliary pattern. Bone marrow biopsy and liver biopsy are other good sites for diagnostic sampling in miliary disease. Computed tomography (CT) and nuclear magnetic resonance imaging of the head, where available, are useful in detecting concomitant tuberculomas and complications such as hydrocephalus. Hyponatremia is present in 37% to 73% of patients<sup>142,143</sup> due to the syndrome of inappropriate antidiuretic hormone secretion.<sup>144</sup> Due to the increased incidence of tuberculous meningitis in HIV-infected people, patients should be offered HIV testing.

The usual CSF findings consist of hypoglycorrhachia (CSF glucose <40 mg/dL) in 32% to 88% of patients,<sup>142,145</sup> elevated protein levels, and a lymphocytic pleocytosis with 100 to 500 cells per milliliter.<sup>146</sup> This pattern of abnormalities is generally the same across all age groups. The fluid is usually clear or ground glass in appearance. Markedly elevated protein levels (>500 mg/dL) and xanthochromic fluid may occasionally be seen in severe cases complicated by hydrocephalus with spinal subarachnoid block. An early predominance of polymorphonuclear leukocytes occurs in 6% to 45% of cases.<sup>133,134</sup>

The CSF glucose characteristically declines as the disease progresses. A rising CSF protein may signal the development of obstruction to CSF recirculation due to worsening basilar or spinal arachnoiditis. With appropriate treatment, the CSF findings normalize in the following order: glucose, CSF protein, and CSF cell counts.<sup>140</sup> CSF abnormalities may take up to 3 to 6 months to resolve completely.<sup>147</sup>

The yield from direct AFB smears of CSF ranges from 0% to 87%.<sup>135,143</sup> CSF mycobacterial cultures are positive in 40% to 83%.<sup>135,148</sup> Examination of fluid from the last tube collected at lumbar puncture, larger volumes of CSF (5–20 mL), or staining the clot (pellicle), if one forms, may increase the yield of direct AFB smears. Newer techniques, including measurement of CSF adenosine deaminase, antibodies against mycobacterial proteins, polymerase chain reaction (PCR) analysis, and assays to detect mycobacterial antigens, have been developed but have not entered widespread use due to limited sensitivity and specificity.<sup>149–151</sup>

A high level of clinical suspicion, however, is necessary to diagnose many cases of tuberculous meningitis. Only one-fourth to one-third of patients will have a history of exposure to a known case of TB, although such information should be sought. The chest x-ray, if consistent with TB, provides an important diagnostic clue. Acid-fast smears and cultures of secretions and tissues from other organs may provide important supportive evidence. Sputum examination should be performed in patients with pulmonary involvement. Cultures of gastric aspirates may be useful alternatives in children. The yields of sputum and gastric aspirate smears and cultures range from 14% to 51%.<sup>134,140</sup>

Lumbar puncture and examination of the CSF form the cornerstones of diagnosis in tuberculous meningitis. The differential diagnosis of subacute or chronic lymphocytic meningitis,

with or without hypoglycorrhachia, is broad and includes fungal meningitis, “aseptic” viral meningitis, parasitic infestations of the CNS, acute syphilitic meningitis, brain abscesses, subdural hematomas, carcinomatous meningitis, and other rarer diseases.<sup>152</sup> The most important differential diagnostic concern in immunocompromised patients is cryptococcal meningitis. The immediate diagnostic value of the lumbar puncture lies in the rapid exclusion of bacterial meningitis and subarachnoid hemorrhage and the demonstration of cell counts and chemistries consistent with tuberculous meningitis. Multiple lumbar punctures (up to three to four taps of 10–20 mL of CSF) are indicated if the diagnosis remains in doubt as the yield from cultures and smears increases with serial taps<sup>135</sup> and the evolution of CSF chemistries and cell counts (development of lymphocytic pleocytosis and progressive fall in glucose) can be followed.

Most of the first-line anti-TB drugs achieve good levels in the CSF. In the presence of meningeal inflammation, isoniazid achieves levels in the CSF comparable to those in the blood.<sup>153</sup> Rifampicin levels are 20% to 50% of those in the peripheral blood.<sup>154</sup> Ethambutol, pyrazinamide, and ethionamide all penetrate into the CNS relatively well. The notable exceptions are the aminoglycosides that penetrate even inflamed meninges poorly.

Modern short-course chemotherapy regimens (described later) including isoniazid, rifampicin, pyrazinamide, and ethambutol achieve good cure rates.<sup>155</sup> Most authorities treat tuberculous meningitis for at least 1 year. Evidence suggests that the adjunctive administration of corticosteroids (given as prednisone 1 mg/kg/day up to a maximum of 60 mg/day or its equivalent for the first 4–6 weeks of treatment) is beneficial in cases of tuberculous meningitis with depressed levels of consciousness, hydrocephalus, stroke, and cranial nerve palsies or other focal neurologic abnormalities.<sup>135,156–158</sup> Corticosteroids may achieve these salutary effects by blunting severe local inflammation with vasculitis and entrapment of small cerebral blood vessels and cranial nerves. The corticosteroid dosage is tapered after 4 to 6 weeks depending on the clinical response of the patient. Antituberculous chemotherapy alone may be adequate in less severe cases.

Elevated intracranial pressure (ICP) and hydrocephalus are common in tuberculous meningitis, especially in children. Ventriculoatrial or -peritoneal shunting procedures may be required for neurologic deterioration despite appropriate antituberculous chemotherapy and ICP-reducing measures, progressively increasing ICP, and the presence of severe hydrocephalus on imaging studies. The overall prognosis is determined by the severity of neurologic involvement at the time of presentation and the duration of illness.<sup>126,132,135,145,159,160</sup> Comatose patients have the highest mortality and the greatest risk of permanent neurologic sequelae.

## Renal and Genital Tuberculosis

Renal TB is typically a disease of young and middle-aged adults. Most cases of renal TB arise by secondary hematogenous spread of bacilli to the renal cortex from pulmonary lesions either at the time of initial TB infection or due to late breakdown of an old caseous focus. Because of the high renal blood flow, some renal seeding probably occurs in nearly all people at the time of primary infection. These small renal lesions become arrested after the development of effective

cell-mediated immunity but may reactivate to produce disease years or decades later.

Renal TB is characterized by caseous lesions that may necrose and destroy functioning renal parenchyma. Lesions heal by scarring, contraction, and fibrosis. Ureteral fibrosis may lead to strictures or hydronephrosis and obstructive uropathy. Renal TB also may present as interstitial nephritis.

Any portion of the lower genitourinary tract can be involved secondarily by antegrade infection from the infected urine.<sup>161</sup> Bilateral disease is frequently present. Acute or chronic renal failure is an uncommon manifestation but can occur when there has been advanced destruction of both kidneys or bilateral ureteral obstruction. The most frequent presenting symptoms are dysuria (34%), hematuria (27%), and abdominal or flank pain (10%).<sup>162</sup> Fever, weight loss, and night sweats and other systemic symptoms are uncommon. Bladder involvement presents with dysuria, nocturia, or sterile cystitis. Renal TB may also be asymptomatic and discovered incidentally during the evaluation of an abnormal routine urinalysis showing sterile pyuria or microscopic hematuria.

The urinalysis was abnormal in 93% of patients in one large series, with hematuria occurring in 12% and hematuria and pyuria in 34%.<sup>163</sup> Urine AFB smears are positive in 50% to 70% of cases, and cultures for *M. tuberculosis* are positive in 25% to 95% of patients.<sup>164</sup> Nearly all patients have reactive PPD skin tests. Approximately three-fourths of patients with renal TB have abnormal chest films consistent with active or remote TB. Intravenous pyelography (IVP) is the standard mode of imaging and allows good visualization of the upper and lower genitourinary tract. The IVP is abnormal in more than 90% of patients, with classic findings suggestive of renal TB present in approximately one-half.<sup>146</sup> Characteristic abnormalities include cortical scarring, papillary necrosis, calcifications, caliceal dilation, and strictures of the collecting system. The ureters may be shortened and dilated (“pipe stem”) or show single or multiple (“beaded”) strictures. Strictures may develop while patients are on anti-TB treatment.

The mainstay of treatment of renal TB is short-course chemotherapy. Concomitant corticosteroid treatment has been advocated by some to prevent ureteral strictures but no controlled clinical trials have been performed. Surgical treatment was once widely used for extirpation of infected necrotic tissue but is now reserved for treatment of complications. Whenever possible, surgical treatment should be delayed to allow completion of 4 to 6 weeks of anti-TB chemotherapy before surgery. Partial or complete nephrectomy may be necessary to remove destroyed kidneys or treat cases of recurrent cystitis. Ureteral dilation and reconstructive procedures may be required to treat ureteral strictures.

The most common sites of involvement of the female genital tract are the fallopian tubes, endometrium, and ovaries.<sup>165</sup> TB of the female genital tract is usually due to hematogenous spread to the affected organs and differs from genitourinary TB in men in this respect. The urinary tract is often not affected. Women with genitourinary TB usually present with menorrhagia, pelvic pain, vaginal discharge, or infertility. The mean age at onset is in the fifth decade of life. Most patients are nulliparous. The general physical examination is often unremarkable. Female genitourinary tract TB can be diagnosed by endometrial biopsy, curettage, or culture of menstrual blood during the first 2 days of flow.

Nearly all males with genital TB present with a mass lesion (usually painless) in the epididymis, prostate, and, less frequently, the testis<sup>166</sup>; 90% have concomitant active renal TB. The diagnosis can be established by biopsy of the lesion.

### Tuberculous Pericarditis

Tuberculous pericarditis arises most frequently by direct spread from involved mediastinal lymph nodes or adjacent pulmonary lesions and from hematogenous seeding. Pericardial effusion is the most common clinical manifestation. Pericardial effusions usually form slowly. In chronic cases, up to several liters of fluid can accumulate with massive pericardial enlargement. The fluid is initially thin and watery but becomes cloudy and more exudative with progressive disease. Healing by fibrosis can result in pericardial calcification and constrictive pericarditis, the most serious complication.

The onset is insidious in three-fourths of cases. Cough, chest pain, dyspnea, orthopnea, pedal edema, and night sweats are the most frequent symptoms. Fever is present in 73% to 97% of patients<sup>167,168</sup> and signs of pericardial disease with cardiomegaly, tachycardia, pulsus paradoxus, muffled heart sounds, hepatomegaly, jugular venous distention, ascites, and peripheral edema occur in 34% to 84% of cases.<sup>167–169</sup> Ten percent of 240 patients in one large series from South Africa presented with acute pericardial tamponade.<sup>170</sup> Concomitant pleural effusions are present in approximately one-half of patients.

The diagnosis may be difficult to confirm. Sputum samples can be examined when pulmonary lesions are present; however, these are absent in many cases. Pericardiocentesis usually reveals an exudative fluid. Direct AFB smears of pericardial fluid are rarely positive and the yield on culture is 50% to 59%.<sup>168,170</sup> Pericardial biopsy with histologic examination and culture of the affected tissue has a higher diagnostic yield of 70% to 83%.<sup>168,170</sup> In high TB prevalence areas, tuberculous pericarditis is usually the most common cause of pericardial disease in adults, and empirical anti-TB treatment may be considered. It is important to note that 5% to 17% of patients in large older case series had negative tuberculin reactions. Tuberculin anergy is even more frequent in immunosuppressed people such as AIDS patients with tuberculous pericarditis. Therefore, the absence of a positive tuberculin skin test does not exclude the diagnosis.

Treatment with standard short-course chemotherapy is effective in most cases. A minority of patients develops congestive heart failure and elevated venous pressure due to constrictive pericarditis; these patients may require pericardiectomy. Early surgical drainage does not alter late progression to constrictive pericarditis or mortality,<sup>170</sup> but does decrease the need for repeat pericardiocentesis and the need for later drainage procedures.<sup>171</sup> Pericardiectomy is indicated for life-threatening or recurrent tamponade or persistently elevated venous pressure.<sup>171</sup> Adjunctive corticosteroid treatment can reduce granulomatous inflammation and decrease later complications. In a placebo-controlled trial of prednisolone (60 mg three times a day for 1 month, 30 mg three times a day for 1 month, 15 mg three times a day for 2 weeks, and 5 mg/day for 1 week) added to short-course chemotherapy in patients with constrictive pericarditis, prednisolone therapy was associated with more rapid improvement in symptoms, decreased need

for pericardiectomy, and decreased mortality.<sup>171,172</sup> Adjunctive corticosteroid therapy also has been shown to decrease mortality in HIV-infected people with tuberculous pericarditis.<sup>173</sup>

### Abdominal Tuberculosis

Although rare in industrialized countries, abdominal involvement by TB is still a common cause of abdominal disease and ascites in developing nations. Gastrointestinal TB usually arises from swallowing infected sputum or drinking unpasteurized milk. *Mycobacterium bovis* may be the etiologic agent in cases acquired by the latter mechanism. *Mycobacterium tuberculosis* and atypical mycobacteria frequently involve the abdominal lymph nodes and viscera in patients with advanced AIDS.

TB can involve the gastrointestinal tract at all levels. Ulcerating masses can occur in esophagus and stomach and present with gastrointestinal bleeding or perforation. The terminal ileum, with its rich submucosal lymphoid tissue, is the area of the bowel most frequently involved by TB. Disease in the distal ileum may mimic Crohn's disease or patients may present with "tuberculous typhlitis" with fever, obstruction, gastrointestinal bleeding, or perforation and an acute abdomen.

Widespread disease with lymph node and serosal involvement presents as tuberculous peritonitis and ascites. Clinical manifestations are described in several excellent reviews.<sup>174,175</sup> Abdominal pain, swelling, weight loss, and anorexia are the most frequent presenting complaints. Sixty-two percent are febrile (often low-grade fever) and 80% have ascites on physical examination.<sup>174</sup> Most cases have an insidious onset, although ascites may accumulate rapidly and a few patients present with peritonitis and an acute abdomen. This indolent presentation must be distinguished from mesenteric spread of primary abdominal cancers with diffuse abdominal carcinomatosis. When symptoms are acute, the diagnosis of TB is often unsuspected and made at the time of laparotomy for suspected cholecystitis, appendicitis, or pelvic inflammatory disease. Findings on physical examination are nonspecific and the classic finding of a "doughy" abdomen with a palpable mass is infrequent. Pathologically, widespread mesenteric thickening, ascites, and tubercles studding the peritoneum, omentum, and other viscera are present.

The diagnosis is difficult in patients without findings of other pulmonary or extrapulmonary disease. PPD skin tests are often negative and do not exclude the diagnosis. The ascitic fluid is usually a clear, straw-colored exudate with a lymphocytic pleocytosis. The fluid may be transudative with little or no elevation of the total protein when TB peritonitis complicates preexisting cirrhosis. The bacillary burden in ascitic fluid is low and AFB smears are usually negative. Culture of small volumes of ascitic fluid has a diagnostic yield of only 40% to 50%<sup>175,176</sup> but increased to 85% when 1 L of fluid was examined.<sup>177</sup> Plain films of the abdomen may show signs of ascites, dilated loops of small bowel, or calcifications. A chest x-ray should always be obtained to search for concomitant pulmonary TB or pleural effusion, which was present in 58% of patients in one large study.<sup>174</sup> Barium studies may show areas of bowel narrowing. Ultrasonography and CT scanning of the abdomen, when available, are useful in demonstrating the presence of ascites and lymphadenopathy and involvement of other viscera. Biopsy is often necessary to

confirm the diagnosis. Blind needle biopsy of the peritoneum has a diagnostic yield of 64% but carries the potential risk of bowel injury and hemorrhage. Open laparotomy avoids these risks, is well tolerated, and is nearly 100% diagnostic. When available, directed laparoscopic biopsy is the diagnostic test of choice. It is safe and allows biopsies to be taken from directly visualized lesions with a diagnostic yield of 84% to 100%.<sup>177,178</sup> Short-course anti-TB chemotherapy regimens are highly effective for the treatment of abdominal TB.

### Other Rare Forms of Tuberculosis

Direct inoculation of the tubercle bacillus into the skin following trauma can produce chancre-like lesions (firm, ulcerating, nontender nodules) in people without prior TB infection or large warty lesions in sensitized people usually involving the hands in adults or the feet in children.<sup>179,180</sup> Lupus vulgaris is another form of cutaneous TB believed to arise by seeding of the skin from another endogenous tuberculous focus. The lesions most commonly involve the neck and face and begin as reddish-brown papules. Large plaques with peripheral “apple jelly” nodules may develop as the lesions grow. The lesions are not painful. The diagnosis is made by biopsy with special stains and mycobacterial culture. High clinical suspicion is essential because tuberculin skin tests are negative in many of these patients and more than half of patients do not have other evidence of active TB.<sup>181</sup>

Ocular forms of TB include ulcerative or nodular conjunctivitis, scleritis, uveitis, and choroidal tubercles. Phlyctenular keratoconjunctivitis, characterized by elevated pink or white nodules at the limbus, is a particular form of conjunctivitis in children that is believed to be a hypersensitivity reaction to mycobacterial proteins and is rarely associated with active TB. Choroidal tubercles are small, round, white or gray lesions in the choroid of the posterior eye pathognomonic of miliary TB.

TB can also involve the larynx, paranasal sinuses, salivary glands, and oral cavity. Laryngeal disease is most frequently, but not always, seen in conjunction with extensive pulmonary TB. Sinus lesions appear as masses or ulcers. The middle ear may be infected by direct spread of bacilli via the eustachian tube or hematogenously. Painless chronic drainage from otitis media is highly suspicious of TB.

Globally, TB is the leading cause of primary adrenal insufficiency. Adrenal gland involvement was present in more than 50% of patients with disseminated TB.<sup>182</sup> Chronic and, rarely, acute adrenal insufficiency may be the presenting signs of tuberculosis.

### PATHOGENESIS AND IMMUNITY

The interaction between *M. tuberculosis* and the host is influenced by the genetics of both. It is assumed that certain humans express enhanced levels of innate resistance, although the immunogenetic basis for this is not understood. Strains of *M. tuberculosis* also differ in their virulence and their induction of host cytokines that may modify the granulomatous tissue reaction as well as the TST. After inhalation, droplet nuclei containing small numbers of viable tubercle bacilli are deposited in the terminal airspaces. The initial site of exposure/infection is most often in the lower or middle lobes due to the higher ventilation of these lung regions. The potential

interaction of ingested bacilli with antibody is an important area of current investigation. In the lung, tubercle bacilli are phagocytosed by alveolar macrophages and dendritic cells. Tubercle bacilli have the capacity to invade alveolar type 2 epithelial cells as well. The initial interactions also involve Toll-like receptors (TLRs) on the phagocyte surface that are ligated by the lipoglycan lipoarabinomannan. Phagocytosis, invasion, and ligation of TLRs result in the production of chemokines that attract blood monocytes and lymphocytes to form an inflammatory focus.

More than half of intensely exposed household contacts fail to manifest *M. tuberculosis* infection presumably due to innate resistance. Bronchoalveolar lavage cells from exposed household contacts demonstrate an increased frequency of *M. tuberculosis*-reactive IFN- $\gamma$ -producing cells that may contribute to local protection. The innate local host defenses that prevent establishment of infection manifest by tuberculin skin test conversion in exposed people are not understood. The current understanding of events associated with the establishment of a latent focus of infection is as follows: In the immunologically naive host lacking sufficient innate resistance, the bacilli have the capacity to multiply intracellularly, ultimately leading to necrotic cell death with release of more bacilli into the alveolar space. T cells drawn to the inflammatory focus do not have immunologic memory. Nonetheless, certain T cell populations (e.g.,  $\gamma\delta$  T cells and natural killer cells) may activate alveolar macrophage and monocyte killing of the bacteria to provide some local control of the infection. Bacilli released by lysed cells spread from the alveolar spaces to the regional lymph nodes, however, and then hematogenously throughout the body.

Subsequent events are determined by the development of specific acquired resistance. In the absence of a competent immune response, tissue inflammation and damage are minimal. The clinical presentation is atypical with predominance of lower lobe disease, noncavitary opacities, and extrapulmonary manifestations. Immunodeficient hosts, infants, and children may develop miliary disease and TB meningitis.

However, more than 95% of infected humans control the infection and have no clinical symptoms. In them, the initial interactions between the bacillus and host cells lead to induction of specific acquired immunity against *M. tuberculosis*. This immunity controls the primary infection and maintains foci of persistent organisms as clinically latent. Macrophages infected with tubercle bacilli and dendritic cells present mycobacterial antigens to T cells with appropriate antigen-specific receptors triggering expansion of memory immune cells. After initial infection with *M. tuberculosis*, alveolar macrophages release multiple cytokines, including IL-1, IL-6, IL-12, TNF- $\alpha$ , and granulocyte macrophage-colony stimulating factor (GM-CSF), as well as the chemokines IL-8 and RANTES (regulated upon activation, normal T cell expressed and secreted), which facilitate recruitment of lymphocytes and monocytes into the lung.<sup>183,184</sup> Pulmonary macrophages also release the deactivating factors IL-10 and transforming growth factor- $\beta$  (TGF- $\beta$ ). The balance of cytokines and receptors expressed by antigen presenting cells determines whether T cell differentiation occurs along the Th1 pathway generally associated with protective immunity or the Th2 pathway in which antibody formation dominates. This nomenclature derives from murine systems, in which CD4 cells comprise

two functionally distinct populations that differ in requirements for costimulatory factors and antigen presenting cells. Th1 cells produce IFN- $\gamma$  and IL-2, enhance macrophage microbicidal activity, and augment DTH. Th2 cells produce predominantly deactivating cytokines, including IL-4, IL-5, IL-6, and IL-10, and favor B cell growth and antibody production. Th1 and Th2 lymphocyte populations have important cross-regulatory functions. For example, IFN- $\gamma$  produced by Th1 cells inhibits proliferation of Th2 cells, whereas IL-10 and IL-4 inhibit Th1 cell function.<sup>185</sup> Humans show similar patterns of cytokine production.

CD4 T lymphocytes play an important role in immune defenses against TB. Depletion of CD4 cells in mice results in uncontrolled BCG infection,<sup>186</sup> whereas adoptive transfer of CD4 cells from sensitized animals confers protection against TB.<sup>187</sup> The risk of developing pulmonary TB and severe forms of extrapulmonary disease correlates with declining CD4 lymphocyte counts in HIV-infected people.<sup>188,189</sup> The tremendously increased risk of reactivation of a clinically latent TB infection in HIV-infected people redefines the concept of latency. Clearly, active immune surveillance involving CD4 lymphocytes is essential for controlling bacterial replication at these sites. In addition to CD4 cells, CD8 cells contribute to protective immunity.<sup>190,191</sup> The role of  $\gamma\delta$  T cells, CD4<sup>+</sup>CD8<sup>-</sup>, and natural killer cells to acquired immunity is unclear. Evidence has emerged supporting a role for antibody in protection, requiring a rethinking of basic concepts of immunity and pathogenesis.<sup>192,193</sup>

As noted previously, *M. tuberculosis* antigen-specific T cells (CD4 and CD8) produce critical macrophage-activating factors, including GM-CSF and IFN- $\gamma$ . Activated macrophages are capable of intracellular killing of mycobacteria and forming granulomas, further limiting dissemination of the organism. A second function of specific T cells is to serve as cytotoxic effector cells to lyse macrophages that are overlaid with bacilli. The organisms thus released are killed either directly or after ingestion by newly recruited activated macrophages. The cytokine TNF- $\alpha$  is produced by cells that are infected with *M. tuberculosis* or exposed to mycobacterial antigens and has diverse roles in TB. It is critical to the formation of granulomas but also contributes to morbidity as a cause of fever, wasting, and hypotension. The development of effective specific acquired immunity responses occurs concomitantly with the development of specific DTH responses demonstrated by a reactive tuberculin skin test, which can usually be detected 4 to 6 weeks after initial TB infection.

In people who develop protective immune responses, the initial focus of infection usually heals by fibrosis or after undergoing caseation and calcification. Regional lymph nodes also heal over several months. Small numbers of viable tubercle bacilli may survive in these foci for decades in a dormant state. Breakdown of these foci in the setting of waning immunity due to aging, immunosuppressive medications, HIV infection, or other medical illnesses as discussed previously can result in reactivation of the previously well-contained infection, leading to clinically apparent disease.

Protective immune responses against TB developed after primary infection usually protect against subsequent exogenous reinfection with other strains of *M. tuberculosis*. Studies using restriction fragment length polymorphism DNA fingerprinting, however, indicate that recent infection and exogenous

reinfection and progressive TB disease may contribute substantially to TB morbidity in densely crowded slums in high-burden countries<sup>194</sup> and in immunocompromised groups such as alcoholics residing in public shelters<sup>195</sup> and HIV-infected patients in large urban areas.<sup>196,197</sup> Reinfection TB has also been documented to occur in HIV-infected people in Africa<sup>19</sup> and may be most important in crowded urban areas of developing countries and in closed environments, principally mines, where high rates of TB disease and transmission occur.

During the period of clinical latency, effective host defenses against the development of active TB are characterized by strong Th1-like patterns presumably reprimed at local sites of bacterial replication. IL-12 appears to be the critical cytokine in the development of protective immunity and IFN- $\gamma$  in its expression. Genetic defects in the expression of these cytokines or their receptors lead to predisposition to disseminated mycobacterial infections.

When the immune host is exposed to mycobacterial antigens as occurs in postprimary and reactivation TB, a brisk in situ DTH response occurs and may contribute to tissue damage. This is the case in pleural TB and TB peritonitis, pericarditis, and meningitis. When the balance between mycobacterial replication and host immunity shifts, usually because of immunosuppression, reactivation TB ensues. At the pulmonary focus there is a vigorous inflammatory response with unregulated expression of cytokines. The immune response no longer controls bacterial replication, contributing instead to tissue damage. The sputum contains high levels of IFN- $\gamma$ , TNF- $\alpha$ , and other cytokines.<sup>198</sup> Patients with progressive TB show a Th2 pattern with depression of DTH, in vitro blastogenesis, and production of IL-2 and IFN- $\gamma$ . Their circulating T cells express IL-4, and serum immunoglobulin G levels to *M. tuberculosis* proteins are increased. The inflammatory response leads to programmed cell death or apoptosis and development of cavities. Systemically, there is overproduction of the immunosuppressive cytokines TGF- $\beta$  and IL-10, which depress IFN- $\gamma$  expression.<sup>199</sup> As patients are treated, the suppression by these cytokines diminishes, unmasking a protracted primary defect in T cell function. This acquired immunosuppression may be a factor in bacterial persistence and the requirement for lengthy courses of chemotherapy as well as the increased risk of reinfection seen in treated TB patients.

With the sequencing of the genome of *M. tuberculosis* it is possible to explore the role of differences in virulence of the organism in pathogenesis. For example, certain strains, such as CDC1551, appear to induce more cytokine production, larger granulomas, and more DTH.<sup>200</sup> The relative role of host and bacterial genetics as opposed to acquired comorbidities in influencing the progression of infection and disease is an area of active research.

## Drug Resistance

Soon after the introduction of streptomycin for the treatment of TB, treatment failures due to drug resistance were noted when patients were treated with single agents. Drug resistance develops from random chromosomal mutations, which occur spontaneously at low rates in wild-type strains of *M. tuberculosis*. The rate of natural resistance varies for specific agents: 1 in  $0.5 \times 10^4$  bacilli for ethambutol, 1 in  $3.5 \times 10^6$  for isoniazid, 1 in  $3.8 \times 10^6$  for streptomycin, and 1 in  $3.1 \times 10^8$

for rifampicin. Combination chemotherapy was introduced in the 1950s to overcome acquired drug resistance by ensuring that sufficient numbers of drugs were given such that all organisms present in a patient were susceptible to one or more of the drugs used. Solid caseous foci contain approximately  $10^2$  to  $10^4$ , whereas cavitory lesions contain approximately  $10^7$  to  $10^9$  bacilli.<sup>201</sup> The probability of a single tubercle bacillus being resistant to more than one drug is the product of the probabilities of resistance to each drug. A cavitory lesion before treatment may already contain 10 to 1000 organisms resistant to a single drug, but it is unlikely that such a lesion contains bacilli resistant to two or more drugs; for example, 1 in  $10^6 \times 1$  in  $10^6$  = only 1 in  $10^{12}$  bacilli would be expected to be resistant to both drugs.

Monotherapy, inappropriate treatment regimens, or the addition of a single drug to the regimen of patients failing treatment select for the outgrowth (clinical resistance) of populations of mutant resistant organisms and the development of multiple drug-resistant TB. The presence of multiple drug resistance limits options for successful treatment and cure of the patient and may lead to the spread of drug-resistant TB to others in the community.

The term *primary drug resistance* refers to the presence of resistance to one or more antituberculous medications in a patient who has never been treated for TB. Primary drug resistance rates are a reflection of natural drug resistance and the successful application of TB treatment by the TB control program in the community. *Acquired drug resistance* refers to drug resistance in patients with a prior history of TB treatment. Acquired drug resistance is often due to poor compliance, poor absorption or bioavailability of drugs, and the addition of single agents to the regimens of patients who are already failing treatment (Box 36-2). Poorly organized TB treatment programs can lead to the rapid development of drug resistance in both developing and industrialized countries.

The term *multidrug resistant* (MDR) TB refers to *M. tuberculosis* isolates resistant to at least isoniazid and rifampicin. The development of rifampicin resistance is a crucial event because overall success rates with four-drug short-course initial and retreatment regimens in patients with isoniazid or streptomycin resistance are only slightly less than those with fully drug-susceptible organisms,<sup>202</sup> whereas treatment outcomes in the presence of both isoniazid and rifampicin resistance are poor. Multiple drug resistance necessitates the use of more toxic, more expensive, and less effective second- and third-line agents for TB treatment. Many developing countries cannot afford these second- and third-line agents.

### Box 36-2 Factors Associated with Acquired Drug Resistance

- Incomplete or intermittent therapy
- Physician error
- Inadequate initial treatment regimen
- Patient noncompliance
- Inappropriate isoniazid preventive therapy (failure to exclude active tuberculosis)

Rates of drug resistance vary widely nationally and regionally and reflect differing methods used in drug-resistance surveys. During the past decade, WHO and the International Union Against Tuberculosis have conducted surveys of resistance rates against first-line anti-TB drugs from 58 countries or regions.<sup>203</sup> Areas of high single and multiple drug resistance have been reported from both industrialized and developing countries. For newly diagnosed patients the median prevalence of resistance to at least one first-line drug in the most recent WHO/International Union Against Tuberculosis and Lung Disease (IUATLD) survey was 11% and ranged from 2% in Uruguay to 37% in Estonia.<sup>203</sup> The median prevalence of MDR TB was 1.0% in new TB cases, with the highest rates of up to 14% in areas of China and the former Soviet Union. The prevalence of drug-resistant and MDR TB is higher in previously treated individuals.<sup>204</sup> Taking a careful history regarding prior TB treatment and exposure to individuals with known drug-resistant TB is the most important way to identify patients at risk for having drug-resistant TB.

### DIAGNOSIS

Routine methods for the diagnosis of TB are based on demonstration of the organism on smears and cultures obtained from infected secretions or tissues from affected organs. Newer methods involve the detection of specific *M. tuberculosis* antigens or antibodies to mycobacterial proteins and the identification of specific *M. tuberculosis* DNA in clinical specimens.

Standard procedures begin with microscopic examination of smears made from potentially infected secretions and tissues and culture of these materials on a variety of media. Hot and cold carbol fuchsin (Ziehl–Neelsen and Kinyoun) methods are the most widely used. The number of bacilli that must be present in a sample for a positive AFB smear has been estimated to be  $10^3$  to  $10^4$ /mL,<sup>3,205</sup> but good laboratories with experienced microscopists who spend adequate time examining slides likely have a lower threshold for detection. The use of fluorochrome stains such as auramine–rhodamine allows more rapid screening of sputum smears with a sensitivity comparable to those of the Ziehl–Neelsen or Kinyoun methods. The rate of sputum smear positivity is dependent on the bacillary load, which is in turn dependent on the extent of disease and the presence of cavitory lesions. Pretreatment smears are negative in 22% to 61% of new pulmonary TB cases and are more common in patients with minimal and noncavitory disease.<sup>206–209</sup>

Clinical specimens can be cultured on a variety of media. The most popular are opaque egg-based Löwenstein–Jensen and clear oleic acid–albumin agar-based Middlebrook media. Löwenstein–Jensen medium is inexpensive but small early colonies can be detected earlier on transparent agar-based media. Cultures should be examined weekly until positive or for 8 weeks. Organisms from positive cultures are then speciated using morphologic and biochemical techniques to identify them as *M. tuberculosis* or atypical mycobacteria. Using conventional egg- or agar-based media, 4 to 8 weeks are required for cultures to become positive, especially for paucibacillary and smear-negative samples. The long culture period is due to the long dividing times of mycobacteria (12–18 hours), which means that 3 or more weeks are required for growth from a single cell to a visible colony on solid media. Drug susceptibility

testing by conventional techniques requires an additional 2 to 4 weeks.

Sputum specimens can be collected at the time of examination, in the early morning, and as overnight pooled collections. Early morning specimens are preferred because these sample the tracheobronchial secretions that have collected in the airways overnight and have a higher yield and a lower contamination rate. Multiple specimens should be examined. The diagnostic yield increases with up to five specimens but most of the enhanced yield is achieved with the first three samples.<sup>210</sup> Sputum can also be induced by the inhalation of normal or hypertonic (3%) saline aerosols in adults unable to spontaneously produce sputum. The resulting secretions are thinner than spontaneously expectorated sputum and the laboratory must be made aware that the sample is an induced specimen to prevent it from being discarded as unsatisfactory. In children and young adults unable to produce sputum, gastric aspiration can be performed, preferably in the early morning before the patient rises, to sample respiratory secretions that have been swallowed and pooled in the stomach. Mycobacteria die quickly in acidic stomach contents, and gastric aspirates should be processed promptly or neutralized with buffer. The sensitivity of AFB smears of gastric aspirates is only 23% to 30%; however, positive smears are highly reliable for the diagnosis of TB.<sup>211,212</sup>

Where available, bronchoscopy is useful for diagnosis in cases in which sputum specimens are repeatedly negative and other samples are unavailable and an empirical trial of treatment is inadvisable. Samples can be obtained by washing, brushing, bronchoalveolar lavage, and transbronchial lung biopsy. Specimens obtained at bronchoscopy are rarely the only positive specimens in patients with TB when final culture results are available.<sup>213–215</sup> The principal value of bronchoscopy, therefore, is in allowing the diagnosis to be established quickly in seriously ill or immunocompromised patients (including patients with AIDS) by demonstrating necrotizing granulomas or AFB in histologic sections of tissue.<sup>118,214–216</sup> Transbronchial biopsy with the fiberoptic bronchoscope may be particularly valuable for the rapid evaluation of suspected cases of miliary disease.<sup>118,125,217</sup>

Newer methods have been developed to shorten the time needed to diagnose TB and perform drug susceptibility testing.<sup>218,219</sup> Systems based on automated or semiautomated detection of growth in enriched liquid media can detect growth more rapidly than detection of visible colonies on solid media. Radiometric culture methods such as the BACTEC 460 system rely on the detection of radioactive <sup>14</sup>C released from a labeled palmitic acid substrate in liquid media by metabolically active mycobacteria and significantly shorten the time until detection of a positive culture. Nonradiometric systems such as the mycobacterial growth indicator tube based on oxygen quenching in the presence of replicating mycobacteria are also entering clinical use. Using appropriate decontamination methods and culture media, it is possible to directly inoculate susceptibility testing media from clinical specimens, eliminating the lengthy primary culture step.

Traditional systems for speciating mycobacteria have relied on biochemical parameters, colonial morphology and rate of growth, and gas or liquid chromatography. Rapid methods using DNA probes have been developed that bind specifically to mycobacterial RNA from a single species; binding

is detected photometrically. Probes are commercially available for *M. tuberculosis* complex (includes *M. tuberculosis* and *M. bovis*), *M. avium* complex, *M. avium*, *M. intracellulare*, *M. kansasii*, and *M. goodii*. These tests require only a few hours to perform.

Ideal diagnostic techniques would allow direct detection of mycobacteria in clinical specimens. The numbers of bacilli in most clinical specimens are small, necessitating the use of concentration methods, very sensitive assays, or procedures that amplify mycobacterial components to detectable levels. Several nucleic acid amplification assays have been developed for mycobacterial diagnosis based on PCR, strand displacement or transcription-mediated amplification, reporter phage, and ligase chain reaction methods. In general, these tests have performed well on smear-positive respiratory specimens (sensitivity, 82%–100%; specificity, 93%–100%) but less so on smear-negative specimens (sensitivity, 51%–88%; specificity, 97%–100%).<sup>218</sup> Molecular amplification tests are expensive and require significant infrastructure and staff training for reliable performance.

Conventional drug susceptibility testing against first-line anti-TB drugs can be performed using the critical concentration or indirect proportion methods on solid media but requires 2 or 3 weeks to perform after a positive culture is obtained.<sup>220,221</sup> The time to obtain results is reduced using enriched liquid culture systems such as the BACTEC 460 system. Resistance to rifampicin is due in the great majority of cases to mutations in a short sequence of the *rpo B* gene of the bacterial RNA polymerase, and rapid PCR-based methods have been developed to assess whether resistance to rifampicin is present. Resistance to other drugs is due to a variety of mechanisms and mutations, and rapid genotypic testing for resistance is not currently feasible. Rapid phenotypic tests for resistance using luciferase reporter phage<sup>222,223</sup> and amplified bacteriophage techniques<sup>224</sup> are also in late development or commercially available. Because they are simpler and use existing laboratory equipment and skills, they may be more affordable and widely applicable.

## TREATMENT

Modern TB treatment is based on the use of potent short-course, multiple-drug regimens that sterilize the sputum rapidly. TB treatment is divided into two phases—the initial intensive phase lasting 1 or 2 months that kills the rapidly dividing, rapidly metabolizing organisms, followed by a 4- to 6-month continuation phase that kills the remaining slowly metabolizing organisms.

The most useful first-line drugs for TB treatment include isoniazid, rifampicin, ethambutol, pyrazinamide, and streptomycin. Adult and pediatric dosages are summarized in Table 36-3. Combination therapy with these agents forms the foundation of current TB chemotherapy.

### First-Line Drugs

#### Streptomycin

Streptomycin was introduced for the treatment of tuberculosis in 1948 soon after its discovery. It must be given parenterally and penetrates most body spaces and tissues, including inflamed meninges. The initial use of streptomycin

**Table 36-3** Dosages of First-Line Antituberculosis Drugs Used in Adults and Children\*

Drug	Daily Dose	Twice Weekly Dose	Thrice Weekly Dose
Isoniazid	5 mg/kg PO (10–15 mg/kg in children); maximum 300 mg/day	15 mg/kg PO (20–30 mg/kg in children); maximum 900 mg/dose	15 mg/kg PO (20–30 mg/kg in children); maximum 900 mg/dose
Rifampicin	10 mg/kg PO (10–20 mg/kg in children); maximum 600 mg/day	10 mg/kg PO (10–20 mg/kg in children); maximum 600 mg/day	10 mg/kg PO (10–20 mg/kg in children); maximum 600 mg/day
Pyrazinamide	Weight 40–55 kg = 1000 mg; 56–75 kg = 1500 mg; above 76 kg = 2000 mg PO (15–30 mg/kg in children); maximum 2 g/day	Weight 40–55 kg = 2000 mg; 56–75 kg = 3000 mg; above 76 kg = 4000 mg PO (50–70 mg/kg in children); maximum 4 g/dose	Weight 40–55 kg = 1500 mg; 56–75 kg = 2500 mg; above 76 kg = 3000 mg PO (50–70 mg/kg in children); maximum 3 g/dose
Ethambutol†	Weight 40–55 kg = 800 mg; 56–75 kg = 1200 mg; above 76 kg = 1600 mg PO (15–25 mg/kg in children);	Weight 40–55 kg = 2000 mg; 56–75 kg = 2800 mg; above 76 kg = 4000 mg PO (50 mg/kg in children);	Weight 40–55 kg = 1200 mg; 56–75 kg = 2000 mg; above 76 kg = 2400 mg PO (25–30 mg/kg in children)
Streptomycin	15 mg/kg IM (20–40 mg/kg in children); maximum 1 g/day	25–30 mg/kg IM (adults and children); maximum 1.5 g/dose	25–30 mg/kg IM (adults and children); maximum 1.5 g/dose

IM, intramuscularly; PO, orally.

\*Children younger than 12 years old.

†Ethambutol is not recommended for treatment in children younger than 12 years old who cannot be reliably monitored for ophthalmologic toxicity but should be considered in cases of drug-resistant tuberculosis.

monotherapy for cavitary TB in the 1940s was quickly followed by the observation that following initial remarkable improvement, after 3 months of treatment up to 80% of patients treated with streptomycin had streptomycin-resistant bacilli.<sup>225</sup> When combined in various regimens with subsequent agents, such as isoniazid, para-aminosalicylic acid, and ethambutol, streptomycin proved highly useful in TB treatment. Streptomycin is a first-line bactericidal agent with a minimum inhibitory concentration (MIC) against *M. tuberculosis* of 8 µg/mL. Streptomycin is usually given by intramuscular (IM) injection at a dose of 15 mg/kg/day (up to 1 g/day) for the first 1 or 2 months of treatment. The drug is renally excreted and the dose should be decreased in patients with underlying renal insufficiency. Major side effects include ototoxicity (vestibular more than hearing loss) and nephrotoxicity and are related to the cumulative dose.

### Isoniazid

Isoniazid (isonicotinic acid hydrazide) was introduced for the treatment of tuberculosis in 1952. Isoniazid is a mycobactericidal drug with an MIC against *M. tuberculosis* of 0.05 to 0.2 µg/mL. It is well absorbed when administered orally (PO) with good tissue and CNS penetration. It can also be administered parenterally by IM injection. Usual doses are 5 mg/kg/day up to 300 mg/day in adults. Higher doses can be given when intermittent dosing is used (twice- or three-times-weekly administration); however, these should not exceed 900 mg/dose because of the increased risk of neurotoxicity, specifically seizures.

The frequency of adverse reactions to isoniazid in HIV-noninfected patients is approximately 5%.<sup>226</sup> The most common

adverse reactions are rash, fever, peripheral neuropathy, and jaundice. Rarer adverse events include neutropenia, thrombocytopenia, seizures, encephalopathy, antinuclear antibody-positive small-vessel vasculitis, dyspepsia, red blood cell aplasia, optic neuritis, methemoglobinemia, urinary retention, and pellagra. Severe and rarely fatal hepatitis may occur during isoniazid preventive therapy. Elevations of serum aminotransferases occur in 10% to 20% of all subjects receiving isoniazid preventive therapy.<sup>227</sup> These increases, developing during the initial weeks of therapy, are generally asymptomatic and frequently resolve despite continuation of the drug. People who consume ethanol (especially on a daily basis), those with pre-existing liver disease, and pregnant and postpartum black and Hispanic women are at increased risk of hepatotoxicity.<sup>228,229</sup> Hepatotoxicity is usually reversible if the medication is stopped when initial symptoms of hepatotoxicity, including nausea, anorexia, malaise, and dull upper abdominal discomfort, occur. Health care workers and patients need to be aware of these symptoms and the importance of stopping INH treatment and seeking medical attention if they occur.

Isoniazid therapy is also associated with the development of a dose-dependent peripheral sensorimotor neuropathy via interactions with pyridoxine and pyridoxal-5-phosphate metabolism. Peripheral neuropathy develops in only 1% to 2% of well-nourished patients receiving 3 to 5 mg/kg/day of isoniazid, but it is also more frequent in malnourished people, pregnant women, and patients with diabetes mellitus, chronic renal failure, and alcoholism. Isoniazid peripheral neuropathy can be prevented or reversed in nearly all cases by supplemental oral pyridoxine 25 to 50 mg/day. Where available, pyridoxine supplementation should be given to all patients receiving INH.

## Rifampicin

Rifampicin is a first-line bactericidal agent that inhibits DNA-dependent RNA polymerase, leading to the death of the bacilli. Rifampicin is well absorbed with good penetration of inflamed meninges. The MIC against *M. tuberculosis* is approximately 0.5 µg/mL. The usual dose is 10 mg/kg/day (up to 600 mg/day). Rifampicin is a potent hepatic enzyme inducer and has many clinically significant drug interactions affecting the dosing of other medications, such as warfarin sodium (Coumadin), theophylline, and HIV protease inhibitors. Rifampicin increases the metabolism of estrogens and can result in decreased efficacy of hormonal contraceptive and breakthrough bleeding. The principal side effects are gastrointestinal intolerance, skin rashes, cholestatic jaundice, and hepatitis. A flulike syndrome characterized by malaise, fever, chills, headache, and myalgias can occur and is more frequent with intermittent dosing. Hemolytic anemia and thrombocytopenia are rare complications but require permanent discontinuation of the drug. Body secretions, including urine, sweat, and tears, appear orange or orange-red during rifampicin treatment.

## Ethambutol

Ethambutol is primarily a mycobacteriostatic agent given to prevent the emergence of drug resistance to other first-line drugs. It has low CSF penetration. The MIC is 1 to 5 µg/mL. Usual dosages are 15 to 25 mg/kg/day. The drug is renally excreted and the dosage should be reduced in patients with renal insufficiency. The most important side effect of ethambutol is retrobulbar neuritis, which presents as blurred vision or decreased peripheral and color vision. The frequency of ocular toxicity is lower at the 15 mg/kg/day dose that is recommended when ethambutol is continued after the intensive phase of therapy. Patients receiving ethambutol should be instructed about symptoms of ocular toxicity. Simple visual acuity and color vision screening at follow-up clinic visits may help detect this complication early. Ethambutol should not be prescribed for young children who cannot report visual symptoms reliably. Ocular toxicity is reversible in most cases after discontinuation of the drug.

## Pyrazinamide

Pyrazinamide is an important first-line bactericidal agent first used in TB treatment in the 1950s. Early concerns about hepatotoxicity relegated it to a minor role until the 1970s, when a series of important clinical trials conducted by the British Medical Research Council clearly established its important role in rapid sterilization of tuberculous lesions with resultant shortening of the duration of chemotherapy from 9 to 12 months to 6 months. Pyrazinamide is highly active in the acidic intracellular environment against organisms in macrophages. It has good tissue penetration, including the CSF. Usual doses are 15 to 30 mg/kg/day, up to 2 g/day. The most frequent side effects are gastrointestinal intolerance, hepatotoxicity, arthralgias, asymptomatic hyperuricemia due to blockade of urate excretion, and, rarely, acute gouty arthritis. Pyrazinamide does not appear to further increase the risk of hepatotoxicity when used in combination with isoniazid and rifampicin.<sup>230</sup> Minor arthralgias occur frequently and can usually be treated with

salicylates or nonsteroidal inflammatory agents such as indomethacin while continuing the drug. The major value of pyrazinamide is its early sterilizing activity against intracellular organisms during the initial intensive phase of treatment.<sup>231</sup>

## Thiacetazone

Thiacetazone is an inexpensive mycobacteriostatic drug that is widely used in developing countries in Africa, usually at a dose of 150 mg/day in combination with isoniazid and streptomycin in a 12-month daily treatment regimen consisting of 1 or 2 months of isoniazid, thiacetazone, and streptomycin followed by 10 months of isoniazid and thiacetazone. It is available in a combination formulation with isoniazid for convenient dosing. Thiacetazone has been associated with an increased incidence of cutaneous drug reactions, including severe Stevens-Johnson syndrome, in HIV-infected children and adults.<sup>232–235</sup> It should be considered a second-line agent when adequate supplies of rifampicin and pyrazinamide are available.

## Second-Line Antituberculosis Drugs

Several other agents are available for retreatment of TB and the treatment of known or suspected drug-resistant TB cases. As a whole, these drugs are more toxic, less well tolerated, and less effective for TB treatment. Their use is indicated only for drug-resistant TB and as substitute agents when first-line drugs cannot be tolerated by the patient. Treatment involving second-line drugs also must be given for long durations of 12 to 24 months. Several of these agents must be given parenterally. Many are not readily available in developing countries due to their expense. Table 36-4 summarizes some important points about these agents.

## Initial Tuberculosis Treatment Regimens

Many national and international organizations have published excellent comprehensive guidelines for TB treatment that are very valuable for clinicians.<sup>236–239</sup> This section discusses general principles of treatment (Box 36-3) and some suggested highly effective short-course regimens. The use of such regimens is feasible and highly cost-effective under program conditions.<sup>240,241</sup> Although the availability of regular supplies of high-quality drugs and the prescribing of adequate regimens in adequate doses for adequate durations are essential, it is important to stress the critical roles of the health care team, patient adherence to treatment, social factors, and political commitment in achieving good outcomes in TB control.

Four drugs should be prescribed initially unless local drug-resistance rates to first-line anti-TB drugs are known to be low (<2%).<sup>236</sup> Treatment with rifampicin, isoniazid, and pyrazinamide is critical to the success of 6-month short-course regimens. Rifampicin and isoniazid should be given for the entire duration of 6-month regimens for optimal efficacy. Pyrazinamide is necessary only during the first 2 months of treatment of drug-susceptible TB. Where available, the use of fixed-dose combination tablets decreases the number of pills to be taken, lessens the risk that patients may take only some of their drugs, and is strongly recommended by WHO.<sup>238</sup>

**Table 36-4** Second-Line Antituberculosis Drugs

Drug	Pharmacokinetics/Mechanism of Action	Daily Dose for Children and Adults (Maximum Dose)	Common Side Effects
Para-aminosalicylic acid (PAS)	Inhibits mycobacterial dihydropteroate synthetase; well absorbed after oral dosing	150 mg/kg/day (12 g) PO	Gastric upset, sodium load, nausea, vomiting, diarrhea
Ethionamide	Structurally similar to isoniazid; well absorbed PO; good CSF penetration; renally excreted	15–20 mg/kg/day (1 g) PO	Gastrointestinal upset, hepatotoxicity, rash
Kanamycin	Binds to 30S subunit of bacterial ribosome; inhibits protein synthesis; given IM; renally excreted	15–30 mg/kg/day (1 g) IM	Ototoxicity, nephrotoxicity
Capreomycin	Similar to other aminoglycosides; given IM; poor CSF penetration; renally excreted	15–30 mg/kg/day (1 g) IM	Nephrotoxicity, ototoxicity
Cycloserine	Analogue of D-alanine; inhibits cell wall synthesis; well absorbed PO	15–20 mg/kg/day (1 g) PO	Psychosis, seizures, depression, headache, personality change, rash, vertigo
Fluoroquinolones (ofloxacin, levofloxacin)	Inhibits topoisomerase II (DNA-gyrase); well absorbed PO; parenteral preparations of some drugs available; renal excretion	PO	Gastrointestinal upset, dizziness, tremor, confusion, seizures, photosensitivity

CSF, cerebrospinal fluid; IM, intramuscularly; PO, orally.

Patient compliance is a crucial factor in treatment failure and the development of acquired drug resistance. Whenever possible, TB treatment should be administered as directly observed therapy (DOT), where a health care worker or lay supervisor observes the patient swallow each dose of medications. DOT has been shown to be a highly effective (and cost-effective) strategy for TB treatment in both industrialized and developing countries.<sup>240,242</sup>

The following 6-month regimens have been shown to be highly effective in initial TB treatment<sup>231,243,244</sup>:

1. Two months of daily isoniazid, rifampicin, ethambutol, and pyrazinamide followed by 4 months of isoniazid and rifampicin administered two or three times weekly
2. Two weeks of daily isoniazid, rifampicin, ethambutol, and pyrazinamide followed by 6 weeks of twice weekly

isoniazid, rifampicin, ethambutol, and pyrazinamide followed by 4 months of twice weekly isoniazid and rifampicin

3. Six months of three times weekly isoniazid, rifampicin, and pyrazinamide

If drug susceptibility testing is performed and the isolate is fully drug susceptible, ethambutol may be discontinued. If the patient cannot tolerate pyrazinamide, excellent results may be achieved in patients with fully susceptible TB with 9 months of isoniazid and rifampicin. Six months of treatment with the previous regimens is generally adequate for patients with pulmonary tuberculosis who have satisfactory clinical and bacteriologic responses to treatment. Based on data suggesting that patients with initial cavitory disease who do not convert their sputum cultures to negative after 2 months of treatment are at high risk for relapse, some authorities now recommend extending treatment for an additional 3 months with INH and rifampicin for such patients.<sup>236</sup>

In developing countries with limited supplies of rifampicin, 2 months of daily ethambutol, isoniazid, rifampicin, and pyrazinamide followed by 6 months of daily isoniazid and ethambutol<sup>238</sup> or 6 months of isoniazid and thiacetazone<sup>239</sup> are widely used, although relapse rates are higher than with regimens containing rifampicin during the entire course of treatment.<sup>246</sup> Longer treatment regimens without a potent rifampicin and pyrazinamide-containing intensive phase, such as 2 months of daily isoniazid, thiacetazone, and streptomycin followed by 10 months of isoniazid and thiacetazone, can also be utilized but are associated with lower cure rates and high rates of cutaneous drug reactions in areas with a high prevalence of HIV coinfection.<sup>233–235,245</sup>

Patients should be instructed to cover their mouth and nose with a handkerchief or tissue when coughing. Masks and

### Box 36-3 Important Principles in Treatment of Tuberculosis

- Use combination chemotherapy with at least two drugs to which the patient's organism can reasonably be expected to be susceptible.
- Never add a single drug to a failing regimen.
- The principal role of bacteriostatic drugs is to prevent emergence of resistant organisms during combination chemotherapy.
- Adequate doses of bioavailable drugs must be given consistently for an adequate duration of time for cure to be achieved.
- Both the patient and the physician share responsibility for successful treatment.

an initial period of respiratory isolation are desirable for hospitalized patients with smear-positive disease, where available. These measures can be discontinued when the number of bacilli visible on sputum smears and cough frequency decrease. Short-course chemotherapy regimens rapidly sterilize the sputum. Sputum smears may take longer to clear than sputum cultures, especially when rifampicin-containing regimens are used. Sputum smear-positive, culture-negative status was observed during the first 4 to 20 weeks of treatment in 20% of patients in one large series.<sup>208</sup> This phenomenon presumably is due to the visualization of nonviable organisms on sputum smears. Adequate respiratory isolation facilities are not available in many hospitals, however, and the primary emphasis in infection control should be on maintaining a high clinical suspicion for TB and the rapid diagnosis and treatment of infectious sputum smear-positive individuals.

Routine monitoring of hepatic function tests is not recommended. Proper patient education about TB, the need for full completion of treatment, and common side effects is important. In addition to DOT visits, patients should routinely be seen in the clinic on a monthly basis to review progress. At a minimum, the sputum should be examined monthly until conversion, at the end of treatment, and whenever clinical symptoms warrant. Seventy-seven percent to 90% of patients treated with rifampicin-containing short-course regimens should be culture negative (more than 75% smear negative) after completing 2 months of treatment, and essentially all should be culture negative after 3 months.<sup>240,247–250</sup> Reduction in cough frequency, resolution of fever and chest pain, and weight gain are the most important clinical signs of response to treatment. Defervescence occurred within 2 weeks in 64% to 93% of patients with pulmonary TB treated with rifampicin-containing regimens.<sup>251,252</sup> Serial chest radiography should not routinely be used to monitor response to treatment. One-fourth to one-third of patients with good clinical and microbiologic responses to treatment have worsening of radiographic lesions during the initial months of treatment. Chest films should be taken when the clinical course is complicated by new hemoptysis, poor response to treatment, or other significant changes in the patient's condition. In cases of poor response to treatment, if the chest film has not improved after 3 months of treatment, noncompliance, malabsorption of anti-TB drugs, drug-resistant TB, an incorrect initial diagnosis, or other concomitant chest disease should be considered. An end-of-treatment film may be helpful as a future baseline for comparison.

Patients should be instructed to return to the clinic promptly for medical attention when symptoms of drug toxicity occur. Early signs of hepatotoxicity (nausea, malaise, anorexia, and upper abdominal discomfort) should be emphasized. Minor drug reactions may be managed symptomatically with continuation of anti-TB treatment. Moderate or severe suspected drug reactions should be treated by discontinuation of TB treatment, appropriate medical management, and serial observation of the patient until the reaction subsides. At the discretion of the treating clinician, stepwise reinstitution of the anti-TB drugs at full dosage beginning with the least likely offending drug may be considered on a case-by-case basis, or alternative drugs may be substituted. The use of desensitization schedules with escalating doses of drugs such as isoniazid is not recommended. The reintroduction process should

not be prolonged to avoid long periods of monotherapy. The implicated drug should be discontinued if the reaction occurs during rechallenge and the regimen modified appropriately by the addition of new replacement drugs. Most adverse drug reactions to anti-TB drugs are reversible upon discontinuation of the offending medication.

There are several promising developments in the treatment of TB. Rifapentine, a long-acting rifamycin, has been shown to be effective when administered once weekly during the continuation phase of treatment in HIV-noninfected patients.<sup>253</sup> New compounds including PA-824, a nitroimidazopyran active against slowly dividing organisms, are in early testing.<sup>254</sup> Newer fluoroquinolones, including levofloxacin, gatifloxacin, and moxifloxacin, are highly active against *M. tuberculosis* and may allow shortening of treatment to less than 6 months. In a trial from India, 4- and 5-month regimens including an initial intensive phase containing ofloxacin, INH, rifampicin, and pyrazinamide were highly successful in patients with smear-positive tuberculosis, resulting in relapse rates of less than 4%.<sup>255</sup>

## Special Situations

### Pediatric Tuberculosis

Microbiologic confirmation of the diagnosis of TB is difficult in young children and the decision to treat is often based on known close contact with an infectious smear-positive case, compatible clinical symptoms and radiographic findings, and lack of response to empirical treatment with broad-spectrum antibiotics targeted against common bacterial pathogens. Regimens used in children are comparable to those in adults with appropriate dose modifications<sup>236</sup> (see Table 36-3). Local formularies should be consulted about available preparations of anti-TB drugs for children. Ethambutol should be avoided in infants and young children who cannot report symptoms of ophthalmologic toxicity. Radiographic and clinical response should be monitored, with improvement expected over 2 or 3 months. Intrathoracic lymphadenopathy may take up to 2 years to fully resolve in children, and the persistence of lymphadenopathy is not, in itself, an indication for prolonged therapy.

### Pregnancy and Lactation

TB treatment regimens used in pregnant and lactating women are similar to regimens used in nonpregnant women.<sup>236,256,257</sup> Few data are available on the potential teratogenicity of pyrazinamide and some programs avoid its use in pregnancy. Isoniazid and rifampicin have good long-term safety records in pregnant and lactating women, and daily treatment with isoniazid and rifampicin for 9 months is highly effective in drug-susceptible TB. Treatment of drug-resistant TB during pregnancy is complex, and such patients should be evaluated by a specialist. Successful treatment of MDR TB during pregnancy has been reported.<sup>258</sup>

The risk of isoniazid hepatotoxicity may be increased during pregnancy and the early postpartum period. Aminoglycosides should be avoided during pregnancy due to the risk of irreversible ototoxicity in the fetus. Pregnant women are more susceptible to development of isoniazid-associated peripheral neuropathy and should receive pyridoxine 25 to

50 mg/day while on TB treatment. Breast-feeding is safe while on TB chemotherapy.<sup>259</sup>

### Extrapulmonary TB

Extrapulmonary TB is associated with lower bacillary burdens than pulmonary disease; therefore, extrapulmonary disease can generally be treated with standard short-course regimens that are effective for pulmonary disease.<sup>243,260</sup> Owing to the serious implications of relapsed disease at sites of potentially limited drug penetration, most clinicians treat miliary, meningeal, and skeletal TB for 12 or more months. Adjunctive surgical debridement and stabilization of bone and joint tuberculosis should be considered in addition to chemotherapy on a case-by-case basis. There is evidence from controlled clinical trials that short courses of corticosteroids (1 mg/kg/day prednisone or the equivalent rapidly tapered over 4 to 6 weeks) may be useful in cases of tuberculous meningitis, pericarditis, and severe serofibrinous pleurisy. Corticosteroids have also been used in cases of extensive pulmonary TB with severe clinical toxicity or acute respiratory failure. Corticosteroids can be given safely in conjunction with anti-TB chemotherapy.

### Tuberculosis Treatment in Human Immunodeficiency Virus–Coinfected Patients

The treatment of choice for pulmonary TB in HIV-infected patients is short-course combination chemotherapy with regimens including isoniazid, rifampicin, ethambutol, and pyrazinamide that are effective in more than 95% of patients with drug-susceptible TB when administered for a full course of treatment.<sup>20,21,23,24,64</sup> Due to increased relapse rates (in some instances with acquired rifampicin resistance) in HIV-infected patients treated with twice-weekly therapy, daily treatment during the intensive phase and at least thrice-weekly treatment during the continuation phase are highly recommended.<sup>261,262</sup> In contrast, regimens that do not include rifampicin as a principal component are associated with an increased incidence of severe cutaneous hypersensitivity reactions, lower rates of sputum conversion, higher treatment failure and relapse rates, and increased mortality compared with rifampicin-containing regimens in HIV-infected patients.<sup>233,245,263</sup>

Compliance is critical to good outcomes in the treatment of TB in HIV-infected people. DOT may be especially valuable in this setting.<sup>264</sup> Ambulatory treatment is fully satisfactory for the majority of patients with uncomplicated disease.

When treated with appropriate regimens, clinical and microbiologic responses to treatment are comparable to responses in HIV-noninfected patients. An extended duration of anti-TB chemotherapy is not routinely indicated in HIV-infected patients<sup>23</sup>; however, the microbiologic response to therapy should be closely monitored with serial sputum examinations. Treatment should be prolonged if the response to treatment is slow or otherwise unsatisfactory.<sup>236</sup>

Rarely, patients being started on anti-TB chemotherapy develop transient worsening of fever, lymphadenitis, cerebral tuberculomas, pulmonary infiltrates, pleural effusions, or other signs and symptoms of TB—so-called paradoxical reactions. Paradoxical reactions occur in HIV-uninfected people but appear to be more frequent in HIV-infected patients and in some studies have occurred more frequently in patients

being started on antiretroviral therapy and anti-TB treatment at the same time.<sup>265</sup> Paradoxical reactions usually occur within the first 2 months of antiretroviral therapy, often during the initial 2 to 3 weeks of treatment, and may be more frequent in patients with low CD4 counts. The cause of paradoxical reactions is unclear; however, they may be due to reconstitution of host immune responses and heightened inflammatory responses after beginning anti-TB and possibly antiretroviral therapy.<sup>266</sup> Clinical deterioration should be ascribed to paradoxical reactions only after careful evaluation for treatment failure, malabsorption, noncompliance, drug toxicity, or another concomitant opportunistic infection. Mild paradoxical reactions are usually self-limited and may be treated symptomatically. Some authorities recommend a short course of several weeks of prednisone or methylprednisolone beginning at 1 mg/kg/day for patients with severe paradoxical reactions.<sup>236</sup>

Two studies of HIV-infected South African and Haitian adults assessing whether secondary prophylaxis with INH after initial treatment could prevent recurrent TB showed a 55% to 82% decrease in recurrent disease in patients receiving INH.<sup>267,268</sup> Patients with advanced HIV infection benefited the most, leading some authorities to recommend expansion of preventive therapy guidelines to include secondary INH prophylaxis in patients with advanced HIV/AIDS living in areas with a high prevalence of TB.

The timing of initiating antiretroviral therapy and the antiretroviral drugs and regimens used in treating HIV-infected patients with TB who are not currently on antiretroviral therapy is an evolving area of clinical practice. Rifampicin is a potent hepatic microsomal enzyme inducer and alters the metabolism of many drugs. Antiretroviral therapy with protease inhibitors and nonnucleoside reverse transcriptase inhibitors has significant drug interaction during rifampicin therapy, resulting in low serum concentrations of the antiretroviral drugs and high rifampicin levels. In severely immunosuppressed patients (CD4 count < 200  $\mu\text{L}^{-1}$ ) deaths due to HIV-related complications may occur early during TB treatment. Therefore, many authorities recommend beginning concomitant antiretroviral therapy early. Rifabutin has fewer drug interactions and, where available, can be used as an alternative to rifampicin. Other options include using antiretroviral therapy regimens including efavirenz and avoiding protease inhibitors initially. For patients with a lesser degree of HIV-related immunosuppression, it may be best to optimally treat TB before beginning antiretroviral therapy. Recommendations and guidelines are rapidly changing and the clinician should consult with a specialist skilled in the treatment of both TB and HIV/AIDS for assistance.

### Drug-Resistant Tuberculosis

From a tuberculosis control program standpoint, drug-resistant *M. tuberculosis* isolates are as infectious and virulent as drug-susceptible strains.<sup>269,270</sup> The clinical presentation of drug-resistant TB is similar to that of drug-susceptible TB; however, drug-resistant TB is difficult to treat and associated with worse outcomes.

Whereas initial isoniazid or streptomycin monoresistance has only minimal impact on the outcome of 6 months of treatment with rifampicin-containing short-course regimens,<sup>202</sup> the presence of rifampicin resistance or resistance to both isoniazid and rifampicin (MDR TB) are serious. Prolonged treatment

with more toxic and expensive agents is required. Although initial studies reporting clinical outcomes among MDR TB patients were discouraging, recent work shows improving trends, with as many as 80% of patients responding to treatment.<sup>271</sup> With appropriate consultation and supervision, community-based therapy for MDR TB has been successful in some settings.<sup>272</sup> Patients have improved outcomes when their treatment regimen contains a minimum of three drugs to which their isolate is susceptible.<sup>273</sup> A single agent should never be added to a failing regimen.

Cases of drug-resistant TB should be managed by specialized units and consultants whenever possible because treatment requires a good laboratory and access to more expensive and toxic drugs. Retreatment of treatment failures, relapses, and cases of suspected drug-resistant TB should be carefully monitored and administered as DOT. Under program conditions, failures and relapses of TB after an initial course of short-course chemotherapy are rarely multiple drug resistant. Routine drug susceptibility testing of initial pretreatment isolates, although optimal, is not absolutely necessary. Patients with acquired drug resistance to isoniazid or isoniazid and streptomycin can still be cured by retreatment regimens such as the standard 8-month IUATLD retreatment regimens consisting of 2 months of streptomycin, ethambutol, isoniazid, rifampicin, and pyrazinamide, followed by 1 month of ethambutol, isoniazid, rifampicin, and pyrazinamide, and concluding with 5 months of daily or three-times-weekly isoniazid, ethambutol, and rifampicin.<sup>239</sup> Drug susceptibility testing should be performed in patients with treatment failure or relapse, especially after unsuccessful retreatment.

The most important management principle in treating patients with resistance to one or more drugs is the administration of at least two new drugs to which the patient's isolate is susceptible. Initial isoniazid monoresistance can be treated with the retreatment regimens described previously; with a 9-month regimen of rifampicin, ethambutol, and pyrazinamide for 2 months followed by rifampicin and ethambutol for 7 months<sup>274</sup>; or with 6 months of rifampicin, ethambutol, and pyrazinamide.<sup>236</sup> Patients whose isolates are resistant to rifampicin alone may be treated with INH and ethambutol for 18 months or INH, pyrazinamide, and streptomycin for 9 months.<sup>275</sup>

Treatment for MDR TB (resistant to at least INH and rifampicin) involves prolonged therapy and the use of drugs with substantial side effects. Patients with suspected MDR TB should be managed in consultation with a specialist experienced in the management of MDR TB. General principles of management include the initial use of five drugs that are likely to be active, including an injectable, until sputum cultures are negative, then continuing with three drugs. The most efficacious (bactericidal) drugs available should be used in adequate and tolerable doses for an adequate duration. If the patient is failing standard short-course treatment with INH, rifampicin, pyrazinamide, and ethambutol and MDR TB is suspected, one approach is to add a fluoroquinolone such as ofloxacin or levofloxacin, an injectable drug such as kanamycin or amikacin, and possibly ethionamide. Authorities recommend continuing treatment for at least 12 to 15 months after sputum culture conversion. In the setting of localized disease, continued sputum positivity, massive hemoptysis, or inability to tolerate medical treatment, surgical resection of diseased lung tissue may

play an adjunctive role in the treatment of MDR TB.<sup>276,277</sup> Detailed information about the treatment of drug-resistant TB can be obtained from several excellent sources.<sup>239,278–281</sup>

## PREVENTION AND CONTROL

### Tuberculosis Control

There are three principal strategies for the prevention and control of TB. Primary preventive measures include BCG vaccination and interruption of transmission, case finding, and treatment. Preventive therapy—the administration of drugs given after a person has become infected by *M. tuberculosis* to prevent the development of active TB—is an approach targeted at secondary prevention of new cases.

Due to their higher bacillary burden, sputum smear-positive people with active TB (50% of all TB cases) are the principal source of TB transmission in the community. The highest priority in TB control programs and the fundamental approach advocated by IUATLD and WHO is the rapid identification and treatment of new cases of sputum smear-positive pulmonary TB detected through passive case finding. Because these infectious cases transmit TB to others, treatment of smear-positive cases benefits the affected individual and the community. When fully implemented, efficient case finding and effective treatment of smear-positive TB cases can quickly reduce mortality due to TB and the incidence of the disease in high-prevalence areas.

### Bacille Calmette–Guérin Vaccination

Bacille Calmette–Guérin is a living attenuated strain of *M. bovis* derived by serial passage in culture by Calmette and Guérin between 1908 and 1918. It is the basis of several inexpensive, safe vaccines widely used for the prevention of TB. BCG is a component of the United Nations Expanded Programme on Immunizations and is the world's most widely used vaccine. It is usually given as a single intradermal injection soon after birth.

Results of 21 large clinical trials of various BCG vaccines have yielded conflicting data about the efficacy of BCG in the prevention of TB. Protective efficacy ranged from –10% to 81% in these studies.<sup>282</sup> Meta-analyses of these studies suggest that BCG vaccines are approximately 50% protective against the development of TB.<sup>283</sup> In some tropical countries, such as Malawi, BCG vaccine protects against leprosy but not TB. The protective efficacy of BCG vaccines against TB was decreased or absent in trials done in countries closer to the equator, possibly due to the higher frequency of naturally occurring infection with nontuberculous mycobacteria in these areas, which may be cross-protective against TB. Several different strains of BCG are used in making BCG vaccines. Genomic studies comparing various BCG strains have identified deletions, duplications, and single nucleotide polymorphisms that may also account for some of the difference in protection among various BCG vaccines.<sup>284</sup> In contrast to data showing variable prevention of pulmonary TB, there is more solid evidence that BCG is approximately 85% effective in preventing miliary and meningeal TB, the two most life-threatening forms of TB, in childhood.<sup>285</sup> The protective efficacy and duration of protection of BCG vaccination in immunocompromised people, such as those infected with HIV, are unclear.

Complications of BCG vaccination are infrequent and consist mainly of local lymphadenopathy or lymphadenitis; disseminated disease is rare. The rate of complications may be slightly higher in HIV-infected people but is still very low,<sup>286</sup> and WHO recommends that BCG vaccination be administered to infants early in life, even when the mother is known or suspected of being HIV infected. BCG vaccination should be withheld only from people with symptomatic HIV infection.<sup>287</sup>

Vaccines against TB that are under development include DNA vaccines, protein and peptide vaccines with new adjuvants, recombinant BCG and other live vectors expressing immunodominant mycobacterial antigens, naturally or rationally attenuated strains of mycobacteria, and nonpeptide vaccines.<sup>288</sup> Several candidate vaccines are entering human testing.

### Treatment of Latent TB Infection

Treatment of latent TB infection, formerly termed TB preventive therapy, has two principal benefits—an individual health benefit through prevention of TB and an important benefit to the community wherein decreased transmission and new *M. tuberculosis* infections will lead to an eventual lowering of case rates in the entire population. Interest in the use of isoniazid to prevent TB disease in people with previous *M. tuberculosis* infection began in the late 1950s. In HIV-noninfected people, 6 to 12 months of isoniazid preventive therapy was clearly shown to provide long-term health benefits. Isoniazid decreases the occurrence of TB by approximately 65% (range, 25%–92%)<sup>289</sup>; protection lasts up to 19 years and may be lifelong.<sup>290</sup>

Effectiveness is strongly correlated with the duration of preventive therapy and patient compliance. Maximal benefit in HIV-noninfected people was observed with 6 to 12 months of isoniazid preventive therapy, with no further advantage resulting from treatment exceeding 1 year.<sup>291</sup> In a large study from Eastern Europe, the protective efficacy of isoniazid preventive therapy in patients with fibrotic residual lesions on chest radiography was only slightly reduced with 6 months of treatment, from 75% to 65%, compared with 12 months of therapy, whereas side effects were more frequent with the longer regimen.<sup>292</sup> Efficacy increases with compliance and was as high as 90% in highly compliant patients in some clinical trials; however, even patients with intermittent compliance over a sustained course of therapy benefit substantially from isoniazid preventive therapy.<sup>12</sup> Based on the previous data, 9 months of treatment with isoniazid is now the recommended regimen for treatment of latent TB infection for children and most adults. Three months of treatment with isoniazid and rifampicin has also been shown to be effective for the prevention of tuberculosis.<sup>293–295</sup>

The principal safety consideration regarding isoniazid preventive therapy is isoniazid-related hepatotoxicity. In a placebo-controlled trial of 6 to 12 months of isoniazid preventive therapy, the overall incidence of hepatotoxicity was 0.5%.<sup>296</sup> The incidence of hepatotoxicity increased with age, from 0.3% in people 20 to 34 years old to 1.2% in patients 35 to 49 years old, and with increased length of therapy. Ethanol consumption (especially on a daily basis), preexisting liver disease, possibly pregnancy, and the postpartum period<sup>228,229</sup> are also associated with hepatotoxicity.

Data from seven controlled clinical trials have shown that preventive therapy is also effective in PPD-positive (PPD  $\geq$  5 mm)

HIV-infected people.<sup>297</sup> Six to 12 months of isoniazid, 3 months of INH plus rifampicin, and 2 or 3 months of rifampicin and pyrazinamide provide approximately 56% to 60% short-term protection against TB. The combination of rifampicin and pyrazinamide is no longer recommended for treatment of latent TB infection because of an increased rate of severe hepatotoxicity and fulminant hepatic failure.<sup>298</sup> PPD-negative and anergic individuals have not been shown to benefit from preventive therapy against TB.<sup>293,299,300</sup>

The duration of the protective effect of TB preventive therapy in HIV-infected people is unknown.<sup>301</sup> Data from Zambia and Uganda suggest that benefits extend for 1 to 3 years<sup>302,303</sup> and may be longer after treatment with rifampicin-containing regimens.<sup>302</sup>

Decisions to prescribe isoniazid preventive therapy should balance the risks of developing active TB and the risk of isoniazid toxicity. HIV-infected people, close household contacts of smear-positive TB patients, and recent PPD skin test converters are among those at highest risk of developing active TB. Other groups of people with positive PPD skin tests for whom TB preventive therapy should be considered are listed in Box 36-4. Active TB must be excluded prior to beginning preventive therapy.

The daily dosage of isoniazid for preventive therapy is 5 mg/kg (10 mg/kg in children) up to a maximum dose of 300 mg. Isoniazid can also be given twice weekly at a dose of 15 mg/kg up to a maximum dose of 900 mg when supervised preventive therapy is warranted, although the protective efficacy of intermittent regimens has not been studied. Pyridoxine 25 to 50 mg/day should be administered to prevent INH-associated peripheral neuropathy. Routine biochemical monitoring of serum transaminases in patients receiving isoniazid preventive therapy is of limited value in people younger than 35 years of age but should be considered in older people, drinkers, and those with underlying liver disease. When serum liver function tests are monitored, discontinuation of isoniazid should be considered if the levels exceed three to five times the upper limit of normal. All people receiving isoniazid preventive therapy should be instructed to seek medical attention if symptoms of hepatotoxicity, such as malaise, dark urine, nausea,

### Box 36-4 Tuberculin Skin Test–Positive Patients for Whom Tuberculosis Preventive Therapy Should Be Considered

- HIV-infected patients and people at high risk for HIV such as intravenous drug users
- Close contacts of new infectious TB cases (especially sputum smear–positive cases)
- Recent purified protein derivative skin test converters
- People with underlying medical conditions placing them at high risk of developing TB (poorly controlled diabetes mellitus, prolonged corticosteroid therapy, leukemia, Hodgkin's disease, head and neck cancer, end-stage renal disease, conditions associated with rapid weight loss, and chronic protein-calorie malnutrition)
- Recent immigrants from countries with a high prevalence of TB
- Institutionalized people (prisons, nursing homes, etc.)

and abdominal pain, develop and should be seen at the clinic at least monthly.

Only limited experience is available with drugs other than isoniazid for preventive therapy in patients who have been exposed to known or suspected cases of drug-resistant TB or where INH was not tolerated. Treatment with 4 months of daily rifampicin<sup>295</sup> has been used in instances in which the index TB case is resistant to INH or in which the patient could not tolerate INH. Six months of ethambutol plus pyrazinamide or pyrazinamide plus ofloxacin have been used as preventive therapy in high-risk patients who were infected after exposure to cases of MDR TB, although side effects, mainly gastrointestinal intolerance, have been frequent with the latter regimen.

## ATYPICAL MYCOBACTERIA

Several species of mycobacteria other than *M. tuberculosis* have been implicated as important human pathogens in the past three decades. Although the number of cases of disease due to these organisms is much less than those due to *M. tuberculosis* in developing countries, atypical mycobacteria are responsible for many serious infections in immunocompromised people in the United States and Europe, including disseminated *M. avium* complex (MAC) disease in patients with advanced AIDS. Several species cause chronic pulmonary disease and lymphadenitis, the most common clinical manifestations of disease in HIV-noninfected people (Table 36-5).

Disease due to representative species will be discussed. The reader is referred to the excellent comprehensive reviews by Wolinsky,<sup>304</sup> Pitchenik and Fertel,<sup>305</sup> and Wallace<sup>306</sup> for further information.

There are several important distinctions between human disease due to nontuberculous mycobacteria and TB. Atypical mycobacteria are less virulent human pathogens and tend to produce disease in immunocompromised people or people with underlying structural lung disease. Pulmonary disease, lymphadenitis, and disseminated disease are the most common clinical manifestations of disease due to atypical mycobacteria. Nontuberculous mycobacteria are environmental organisms and many species can be isolated from soil, water, dust, milk, and birds or animals in temperate climates. There is little evidence of human-to-human transmission of these organisms, and patients with atypical mycobacterial disease are generally not considered infectious to others. Lastly, many of these organisms can colonize humans without producing invasive disease.

Nontuberculous mycobacteria are usually classified based on the rapidity of growth on solid media and the production of pigment when incubated in light (photochromogens) or darkness (scotochromogens; Runyon classification). Photochromogens (group I) include *M. kansasii*, *M. marinum*, and *M. simiae*; scotochromogens (group II) include *M. scrofulaceum*, *M. szulgai*, *M. xenopi*, *M. gordonae*, and *M. flavescens*; nonchromogens (group III) include *M. avium-intracellulare*, *M. ulcerans*, *M. gastri*, *M. terrae*, *M. triviale*, and *M. malmoense*; and rapid growers (group IV) include *M. fortuitum*, *M. abscessus*, *M. chelonae*, and *M. smegmatis*. Nontuberculous mycobacteria cannot be reliably distinguished from *M. tuberculosis* by AFB smear microscopy and positive smears should be presumed to indicate active TB until proven otherwise. Speciation is difficult and time-consuming and was previously done only by reference laboratories using colonial morphology, pigment

**Table 36-5 Common Disease Syndromes Associated with Atypical Mycobacterial Species in Humans**

Syndrome	Species
Chronic pulmonary disease	<i>M. avium-intracellulare</i> (MAC) complex <i>M. kansasii</i> <i>M. abscessus</i> <i>M. xenopi</i> <i>M. fortuitum</i> complex <i>M. simiae</i> <i>M. malmoense</i> <i>M. szulgai</i>
Skin and soft tissue infections	<i>M. marinum</i> (swimming pool or fish tank granulomas) <i>M. fortuitum</i> complex <i>M. chelonae</i> <i>M. abscessus</i> <i>M. ulcerans</i> (Buruli ulcer) <i>M. haemophilum</i>
Skeletal infections	<i>M. fortuitum</i> complex MAC complex <i>M. kansasii</i> <i>M. marinum</i> <i>M. terrae</i>
Lymphadenitis	MAC complex <i>M. scrofulaceum</i> <i>M. fortuitum</i> complex <i>M. malmoense</i> <i>M. kansasii</i> <i>M. haemophilum</i> <i>M. genavense</i>
Disseminated disease	MAC complex <i>M. kansasii</i> <i>M. scrofulaceum</i> <i>M. fortuitum</i> complex <i>M. chelonae</i> <i>M. haemophilum</i>

production, and biochemical testing methods. Recently, several species- or species group-specific DNA probes have become available (GenProbe) that allow rapid differentiation of *M. tuberculosis*, *M. kansasii*, MAC, and the common laboratory water-borne contaminant *M. gordonae*.

## Lymphadenitis

Nontuberculous mycobacteria are a common cause of pediatric cervical lymphadenitis. Most children present with unilateral submandibular and high anterior cervical lymph node enlargement.<sup>98</sup> Most are afebrile, appear healthy, and no immunologic abnormalities can be detected. The pathogenesis is unclear but may be related to oropharyngeal trauma from teething and the fact that young children commonly put objects in their mouths. MAC is now the most frequently recovered species, replacing *M. scrofulaceum* and *M. fortuitum*.<sup>98</sup> Many children with nontuberculous lymphadenitis have positive PPD skin tests. Tuberculin skin tests may be useful in suggesting an underlying mycobacterial cause of the enlarged nodes but are not helpful in distinguishing cases due to *M. tuberculosis* and other nontuberculous mycobacteria. The chest

x-ray is usually normal in children with lymphadenitis due to nontuberculous mycobacteria. A tuberculous cause is more likely when associated pulmonary stigmas are present and the supraclavicular and posterior cervical nodes are affected.

The treatment of choice is surgical—total excision of the affected nodes. Incision and drainage and simple biopsy are not recommended because they frequently result in the formation of chronically draining fistulas and sinus tracts requiring difficult cleanup surgery. Antibiotic treatment has not previously been shown to be useful; however, experience with regimens that contain newer agents, such as clarithromycin and fluoroquinolones, has been limited and these drugs may play a role in the future treatment of this condition.

### Skin and Soft Tissue Infections

*Mycobacterium marinum* causes chronic papular lesions and cellulitis when inoculated into the skin traumatized in association with exposure to fresh or saltwater marine environments, including fish tanks. Tenosynovitis can occur if deeper structures are injured, and rarely a sporotrichoid picture with nodules developing proximal to the site of the initial lesion may occur. The diagnosis is made by history, a consistent appearance of the lesion, and biopsy and culture. *Mycobacterium marinum* grows best at low temperatures, and culture at 28 to 30°C (rather than 37°C) is required for optimal isolation. *Mycobacterium haemophilum* and *M. fortuitum* also produce nodular skin lesions, usually in severely immunocompromised people. Deep chronic lower extremity skin ulcers are produced by *M. ulcerans* in tropical Africa (Buruli ulcer) and Australia. *Mycobacterium ulcerans* produces a potent family of toxins, the mycolactones, which are responsible for the severe, protracted local tissue destruction.<sup>307</sup> *Mycobacterium kansasii*, *M. fortuitum*, *M. chelonae*, and MAC can also produce skeletal disease, frequently involving the hand, which resembles TB but usually requires surgical treatment.

### Chronic Pulmonary Disease

MAC, *M. kansasii*, *M. malmoense*, *M. fortuitum*, *M. xenopi*, and *M. chelonae* are the most common nontuberculous mycobacteria causing chronic respiratory disease. Concomitant chronic obstructive pulmonary disease (COPD), pneumoconioses (especially silicosis), chronic bronchiectasis, head and neck and lung cancers, and alcoholism are recognized risk factors for disease due to nontuberculous mycobacteria. Fast-growing species such as *M. fortuitum* and *M. chelonae* sometimes produce chronic pneumonia in patients with rheumatoid lung disease, achalasia, cystic fibrosis, and underlying lipid pneumonia. Nontuberculous mycobacteria may also colonize the lower airway without producing invasive disease, especially in the presence of other chronic structural lung diseases. Therefore, care must be taken to distinguish between colonization and invasive disease. Bronchoscopes and respiratory therapy equipment can become contaminated with water-borne nontuberculous mycobacteria if not properly decontaminated between uses. Diagnostic criteria established by the American Thoracic Society for the diagnosis of nontuberculous mycobacteria as etiologic pathogens in patients with compatible clinical and radiographic findings require persistently positive AFB

smears and isolation of the organism by moderately heavy growth in culture from two or more sputum or bronchoscopic specimens and the exclusion of other possible causes such as TB or other endemic mycoses such as histoplasmosis or cryptococcosis.<sup>308</sup> Despite retrospective series claiming subtle differences between the chest radiographic findings in pulmonary diseases due to nontuberculous mycobacteria and *M. tuberculosis*, in day-to-day clinical practice the radiographic findings in these two conditions are indistinguishable. Apical fibrocavitary disease with scarring, contraction, and volume loss are the most common findings.

### Disease Due to *M. avium-intracellulare* Complex

The MAC is a group of slowly growing mycobacteria that cause cervical lymphadenitis and chronic, slowly progressive necrotizing pneumonia in HIV-noninfected children and adults, respectively, and disseminated disease in patients with AIDS.

### Chronic Pulmonary Disease

Clinical series from the pre-HIV era emphasized the role of MAC as a cause of chronic necrotizing apical pneumonia similar to TB in elderly men with COPD, bronchiectasis, remote TB, or lung cancer.<sup>309</sup> The underlying lung disease was believed to predispose to colonization with MAC, which then resulted in a chronic, slowly progressive, necrotizing pneumonia in a small number of individuals. Patients presented with chronic productive cough, weight loss, fever, and night sweats with fibrocavitary infiltrates on chest film.

In industrialized countries such as the United States, the prevalence of chronic pulmonary disease due to MAC appears to be increasing<sup>310</sup> for unclear reasons, and the spectrum of disease has widened recently. MAC disease has been described as presenting as slowly progressive middle lung field noncavitating nodular infiltrates and persistent cough without fever or weight loss in middle-aged, nonsmoking women with no prior history of respiratory disease.<sup>311,312</sup> Fibrocavitary lesions are much less common in these patients. Chest CT scans demonstrated nodular interstitial disease and bronchiectasis in these patients, which was believed to be due to the nontuberculous mycobacterial disease. Many of these patients succumbed to slowly progressive respiratory failure.

Treatment of pulmonary MAC disease requires prolonged multiple-drug chemotherapy. The organism is highly resistant to many drugs used to treat TB. Recurrence after treatment is frequent. The course of the disease and long-term outcome vary significantly among patients; however, substantial morbidity is common and some patients die of slowly progressive respiratory failure and cor pulmonale. In HIV-noninfected people, cavitary lung disease due to MAC is often indolent, and in some patients noncavitary disease improves or resolves without treatment. In people with concomitant lung diseases such as bronchiectasis or COPD, treatment of the underlying condition with smoking cessation, bronchodilators, and antibiotics should be optimized. MAC is resistant in vitro to many antibiotics. When treatment is necessary, multiple drugs should be used and, when possible, isolates should be submitted to a reference laboratory for susceptibility testing. The new azalide and macrolide antibiotics, azithromycin and clarithromycin, are highly active against MAC. One suggested

initial regimen is clarithromycin or azithromycin, rifampicin, ethambutol, and amikacin or streptomycin for 2 or 3 months followed by clarithromycin or azithromycin, rifampicin, and ethambutol for a total of 24 months.<sup>313</sup> Treatment of pulmonary MAC disease must be prolonged. Side effects are frequent, and early consultation with a unit experienced with the management of these patients is advised whenever possible.

### Disseminated Disease in Human Immunodeficiency Virus-Infected Patients

Although TB is the most common serious mycobacterial disease affecting HIV-infected people worldwide, disseminated MAC infection is a common late opportunistic infection among HIV-infected people in the United States and Europe. The incidence of disseminated MAC disease has decreased greatly due to the advent of highly active antiretroviral therapy and effective chemoprophylaxis. Disseminated MAC disease has been infrequently reported in HIV-infected patients from developing countries in Africa,<sup>314,315</sup> despite the fact that the organism is present in great numbers in the soil and water.<sup>316</sup> Disseminated MAC infection in patients with AIDS usually presents with fever, chronic diarrhea, night sweats, anorexia, hepatosplenomegaly, abdominal lymphadenopathy, fatigue, and weight loss.<sup>317</sup> Severe anemia and elevated serum alkaline phosphatase are often present. In contrast to HIV-noninfected patients, significant pulmonary disease due to MAC is uncommon in patients with AIDS.

Disseminated MAC infection occurs late in the course of HIV infection and contributes significantly to morbidity and mortality.<sup>318,319</sup> The median peripheral blood CD4 lymphocyte count at the time of diagnosis in several studies was less than 50/ $\mu$ L, and disseminated MAC infection has been reported only rarely in patients with CD4 counts greater than 100/ $\mu$ L. The pathogenesis of disseminated MAC infection in AIDS is unclear. The frequent isolation of MAC from the sputum or stool of patients with AIDS before the diagnosis of disseminated MAC disease suggests that primary infection via inhalation or ingestion of the organism usually precedes disseminated disease.

The diagnosis of disseminated MAC infection in AIDS is usually straightforward. Blood cultures are positive in more than 90% of cases; bone marrow, liver, and lymph node biopsies also have very high diagnostic yields. Although MAC has significant in vitro resistance to many antimycobacterial drugs, treatment with newer drug regimens has led to improvement in symptoms, clearing of mycobacteremia, and increased survival. The new macrolides and azalides, clarithromycin and azithromycin, are highly active against MAC. Combination therapy with clarithromycin 500 mg twice daily or azithromycin 600 mg once daily plus ethambutol 15 mg/kg/day is highly effective. The addition of an aminoglycoside<sup>320</sup> or rifabutin<sup>321</sup> adds little to the effectiveness of treatment with a macrolide plus ethambutol. Rifabutin has significant interactions with many antiretroviral drugs. Chemoprophylaxis against disseminated MAC infection is now recommended by many authorities for HIV-infected people whose CD4 lymphocyte counts are less than 50/ $\mu$ L.<sup>322</sup> Azithromycin 1200 mg once weekly and clarithromycin 500 mg twice daily are the most widely used regimens and decrease the incidence of disseminated MAC infection by approximately 60%.<sup>323,324</sup> Rifabutin can be

used alternatively for preventive therapy in people who are intolerant of macrolides but is less effective. Data from several clinical trials have shown that chemoprophylaxis against MAC can be safely discontinued in patients who have a sustained increase in their CD4 count to greater than 100/ $\mu$ L for more than 3 months after beginning antiretroviral therapy.

### Disease Due to *M. kansasii*

*Mycobacterium kansasii* causes chronic pulmonary disease similar to reactivation TB and disseminated disease in patients with advanced AIDS. Disease due to this pathogen occurs sporadically throughout the world but is most common in the central and southwestern United States and in England and Wales. In HIV-noninfected patients with pulmonary disease, treatment with isoniazid, rifampicin, and ethambutol for 18 to 24 months or until sputum cultures have been negative for 12 months is recommended.<sup>308</sup> *Mycobacterium kansasii* usually responds well to treatment. The duration of therapy required in patients with AIDS is unknown.

### Treatment

Treatment of disease due to nontuberculous mycobacteria is long and difficult. Few clinical trials have been done to guide therapy. Atypical mycobacteria are usually resistant to most anti-TB drugs, although several other classes of chemotherapeutic drugs have activity against some species. The value of drug susceptibility testing in guiding treatment is controversial, and reliable testing is available only through a few specialized laboratories. Susceptibility testing is best established in the treatment of *M. kansasii* disease and for assessing susceptibility to macrolides and azalides for MAC infection.

The effectiveness of drug therapy is highly variable, even with combination therapy. Thorough surgical debridement is important in localized disease. *Mycobacterium marinum* infections limited to superficial tissue can be treated with doxycycline, trimethoprim-sulfamethoxazole, or ciprofloxacin. Deeper or extensive infections require treatment with combination therapy with rifampicin, ethambutol, and possibly streptomycin. Sulfonamides, cefoxitin, amikacin, ciprofloxacin, and imipenem are active against *M. fortuitum*. Infections due to *M. scrofulaceum* should be treated with the same regimens used for MAC infections.<sup>325</sup> Treatment of MAC and *M. kansasii* infections was described earlier. The reader is encouraged to consult the published guidelines of the American and British Thoracic Societies for detailed information about the treatment of specific mycobacterial infections.<sup>308,326</sup>

# Mycobacterium ulcerans Infection (Buruli Ulcer)

WAYNE M. MEYERS  
FRANÇOISE PORTAELS

## INTRODUCTION

Buruli ulcer (BU), caused by *Mycobacterium ulcerans*, is an indolent necrotizing infection of the skin, subcutaneous tissue, and bone. Synonyms for BU are Bairnsdale or Searles' ulcer in Australia, and Kumusi ulcer in Papua New Guinea. Clancey and associates named the disease after the geographic area of the first large epidemic investigated, located in Buruli County, Uganda.<sup>1</sup> The disease was first described in 1897 by Cook in Uganda.<sup>2</sup> Because BU often appears in forms other than ulcers, most investigators prefer the term *M. ulcerans* disease. BU is the third most common mycobacterial infection of humans, after tuberculosis and leprosy. The World Health Organization (WHO) in 1998 recognized BU as a re-emerging infection, most pronounced in West African countries, where the disease is a major public health problem, primarily because of frequent disabling and stigmatizing complications.<sup>3,4</sup>

## AGENT

MacCallum and colleagues were the first to isolate *M. ulcerans* in culture in 1948 in Australia.<sup>5</sup> The organism is an acid-fast bacillus (AFB) that grows optimally at 30° to 32°C on mycobacteriologic media such as Löwenstein-Jensen medium and is a slow-grower. *M. ulcerans* is microaerophilic, exquisitely sensitive to ultraviolet radiation, and sensitive to temperatures of 37°C or higher; these properties are consistent with the concept that in nature, especially tropical environments, the organism proliferates in the depths of stagnant water (swamps or ponds) as a saprophyte, symbiont commensal, or parasite.<sup>6</sup> *M. ulcerans* and *Mycobacterium marinum* share many common properties other than environmental sources and low optimal growth temperatures; for example, their mycosides are identical, and molecular biologic properties are similar.<sup>7-9</sup>

The necrotizing and immunosuppressive toxic macrolide elaborated by *M. ulcerans* is a polyketide known as mycolactone.<sup>10-13</sup> A cluster of genes in a plasmid of *M. ulcerans* encodes polyketide synthases and polyketide-modifying enzymes that produce mycolactone.<sup>14</sup> Variations of the 16S rRNA gene sequences of *M. ulcerans* are related to geographic origin

and divide the species broadly into African, American, Asian, and Australian strains.<sup>15</sup> Insertion sequences, apparently specific for *M. ulcerans*, are available for identification of the organism by PCR.<sup>16</sup>

## EPIDEMIOLOGY

With few exceptions, BU is focally endemic in rural wetlands of tropical countries, especially in terrain that has seasonal flooding. A few individuals acquire the disease outside of tropical latitudes: southern Australia, China, and Japan.<sup>17-19</sup> Reported incidence rates currently are highest in West Africa (Benin, Burkina Faso, Côte d'Ivoire, Ghana, Guinea, Liberia, Nigeria, and Togo).<sup>20</sup> Other endemic countries include Malaysia, Indonesia, Papua New Guinea, Peru, Suriname, French Guiana, Cameroon, Republic of the Congo, Equatorial Guinea, Gabon, Angola, Democratic Republic of Congo, Sudan, and Uganda.<sup>21,22</sup> Recent re-emergence of BU is most often attributed to environmental changes: deforestation, topographic human-made alterations (dams, irrigation systems), and increasing numbers of people doing manual basic agriculture in wetlands.<sup>23</sup>

Highest frequencies (approximately 75%) are in children 15 years of age and younger, and in the elderly. For all ages, genders are affected equally and no racial predisposition is known.<sup>24,25</sup> Most lesions are on the limbs, with highest frequencies on the lower extremities. Anecdotal observations on genetically related siblings in families of multiple parentage suggest inherited predisposition factors, but none has been identified.

Increasing evidence links the etiologic agent to flora and fauna of stagnant or slow-flowing water.<sup>20,26,27</sup> *M. ulcerans* was first identified in 1999 in aquatic insects and other water-dwelling animals by molecular biologic methods.<sup>6</sup> Culture of *M. ulcerans* directly from the environment has been achieved but is extremely difficult (Portaels and coworkers, unpublished data). There are no reports of transmission from patients to contacts; each patient is exposed from environmental sources, making the distribution of cases random in endemic foci. In Australia, koalas and possums acquire BU in nature.<sup>6,28</sup> An *M. ulcerans*-like organism (*Mycobacterium liflandii*) causes naturally acquired disease in laboratory colonies of African tropical clawed frogs (*Xenopus tropicalis*).<sup>29</sup> This frog is native to some countries with endemic BU. Rats, mice, cows, armadillos, and other animals are susceptible experimentally.<sup>30</sup>

Mode of transmission is an active area of inquiry. With the initial discovery of *M. ulcerans* in water bugs (*Naucoris* spp. and *Blastomatidae* spp.) in Benin, West Africa, insects have been implicated as reservoirs of transmission.<sup>6</sup> Passage of *M. ulcerans* to mice by the bite of infected water bugs has been reported, suggesting that these insects may play a role in natural transmission.<sup>31</sup> However, many lesions in humans arise at sites of antecedent trauma, rendering it likely that the skin at the site was superficially contaminated by *M. ulcerans*, which was inoculated into the skin or subcutaneous tissue by the trauma.<sup>32</sup> Reported trauma has been as severe as gunshot or land mine wounds or as slight as a hypodermic injection. BU has followed at the site of a human bite and a snakebite.<sup>33,34</sup> Contamination of the skin may result from direct exposure to stagnant water, aerosols, insect bite or insect saliva or feces, or from fomites. There are multiple reports of patients with BU

in nonendemic countries, for example, Canada, France, Germany, and the United States.<sup>35-39</sup>

## DISEASE

Following estimated times of inoculation of the etiologic agent, initial lesions appear in the skin from about 2 weeks to approximately 3 years later, or even longer.<sup>32</sup> Mean incubation periods are estimated to be 2 to 3 months in most large series of reported patients. Anecdotal evidence of markedly prolonged onset of disease after leaving an endemic area suggests that latent infection is possible. Connor and Lunn in 1966 were the first to describe the clinicopathology of a large number of patients, in Uganda.<sup>40</sup>

*M. ulcerans* disease presents in a spectrum of forms. A proposed schema for the classification of these forms and their natural history is presented in Figure 37-1. After infection, the disease may remain localized, by developing a nodule that eventually ulcerates, or may disseminate directly, bypassing the nodular stage.

### Localized Disease

#### Nodule

This form develops as a single, usually movable, nodule in the subcutaneous tissue and lower dermis (Fig. 37-2). Nodules are firm, may attain a diameter up to 2 to 4 cm, and though sometimes pruritic, are not painful. This stage often is observed in African patients, and because of the firmness, in the Kikongo language the disease is called “mputa matadi,” or rock-hard lesion.

Microscopically, there is contiguous coagulation necrosis of the lower dermis and panniculus and sometimes the fascia. Deep in the central portion of the lesion there are clusters of AFB. Significantly, the necrosis extends far beyond the location of the AFB. Some nodules contain mineralized foci and vasculitis. There are remarkably few inflammatory cells in the lesion.

**FIGURE 37-2** Nodular form of Buruli ulcer with incipient ulceration in a child in Ghana.

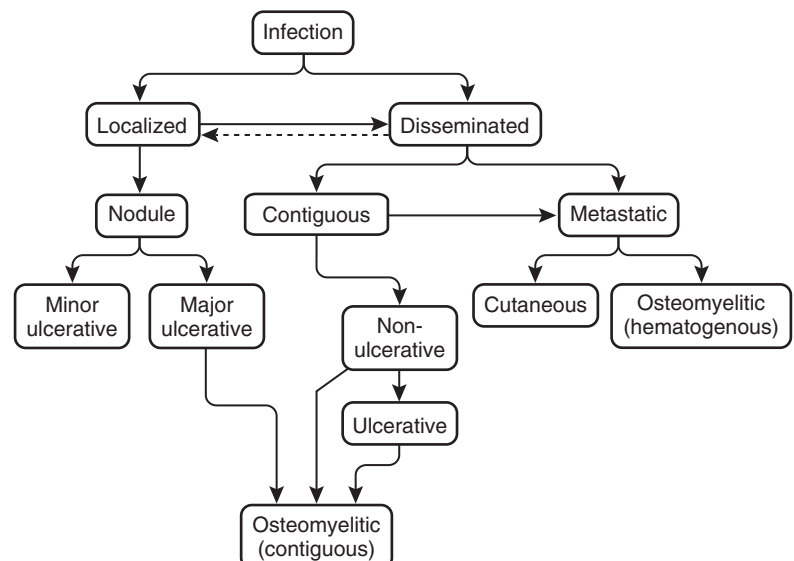

### Nodulo-ulcerative Forms

**Minor Ulcer.** This small ulcer (1 to 2 cm in diameter) arises at the site of a nodule, has a slightly undermined edge, has a necrotic center, and is sharply demarcated (Fig. 37-3). The ulcer tends to self-heal early. No complications such as local osteitis or dissemination from this form have been reported.

Microscopically, there is an ulcer with narrow, undermined edges. The central necrotic slough is sharply defined at the edges and contains large numbers of AFB. This slough is extruded through the ulceration, and scarring ensues.

**Major Ulcer.** Like the minor ulcer, this form arises by ulceration of the epidermis over a nodule (Fig. 37-4). When fully developed, the pristine ulcer has well-demarcated, undermined edges surrounded by a zone of induration. If the lesion is advanced, there is desquamation and hyperpigmentation of the surrounding epidermis. The ulcer base contains

**FIGURE 37-1** Proposed classification of clinical forms of active *M. ulcerans* disease.

**FIGURE 37-3** Minor ulcerative lesion of Buruli ulcer on the leg of a 3-year-old child in Benin. The lesion has nearly healed without treatment.

a whitish necrotic slough resembling cotton wool; hence in Benin, West Africa, the Holi word for BU is “tefoun-tefoun” (cotton-like).<sup>41</sup> Major ulcers may be large when first seen and may destroy wide areas of skin and important structures such as eyes and genitalia. Healing often results in cicatricial contractions, which can be disabling when located over articulations. Contiguous osteitis sometimes develops subjacent to the ulcer and destroys bone. Metastatic disease may spread from such lesions, but not so frequently as in the directly disseminated disease (see later discussion).

In Australia, the initial lesion occasionally presents as a painless pustule less than 1 cm in diameter with erythema in the surrounding skin.<sup>42</sup> The pustule may progress to a major ulcer. This type of BU lesion has not been reported in Africa or any endemic country other than Australia.

Microscopically, there is an ulcer with undermined reepithelializing edges. Adjacent epidermis is often hyperplastic. In the ulcer base and surrounding tissue there is contiguous coagulation necrosis down to and including the fascia (Fig. 37-5). In the panniculus the fat cells are swollen and dead, but their ghost outlines are retained. The interlobular

**FIGURE 37-4** Major ulcerative form of Buruli ulcer in an Angolan man covering entire epigastrium. Note the central slough and undermined and indurated borders.

**FIGURE 37-5** Movat-stained section of edge of ulcer from lesion in Figure 37-4 ( $\times 2.5$ ). There is re-epithelialization of the undermined flap, with contiguous coagulation necrosis of the subcutaneous tissue.

septa are necrotic and thickened. Vasculitis is common. Clusters of AFB are usually plentiful and always extracellular (Fig. 37-6).

## Disseminated Disease

### Plaque

Plaques are elevated, indurated lesions with irregular but rather well-delineated borders. Lesions measure more than 2 cm in diameter and can be 15 cm or more in largest dimension. Skin is reddened or discolored. Plaques may arise from a nodule, but usually there is no historic or histopathologic evidence for a nodule. In late stages, plaques may break down and develop into one or more irregular, ragged ulcers (Fig. 37-7). The appearance of these ulcers differs strikingly from the sharply defined, more or less symmetrical ulcers that develop from localized disease. Microscopically, there is contiguous coagulation necrosis of the panniculus, extending into the dermis and fascia. AFB are confined largely to the panniculus and fascia. Vasculitis and mineralization are common.

**FIGURE 37-6** Subcutaneous tissue of a major ulcer. There are islands of dead fat cells (ghosts) and massive numbers of acid-fast bacilli in an area of coagulation necrosis. Ziehl-Neelsen stain,  $\times 25$ .

**FIGURE 37-7** Plaque/edematous lesion extending from wrist to axilla with a large ragged ulcer at the elbow of a 10-year-old boy in Benin.

### Edematous Form

The edematous lesion is characterized by diffuse, firm, nonpitting thickening of the skin, with margins that frequently are clinically imperceptible. Lesions are not painful. Often there are color changes of the skin. Size of lesions ranges from small (5 cm in diameter) to massive, sometimes involving an entire extremity or even most of the trunk. There usually is no history or microscopic evidence of a nodule.<sup>43</sup>

Microscopically, there is massive contiguous coagulation necrosis similar to that of the other forms already mentioned. AFB are most plentiful in the deepest layers of the panniculus and fascia. Many lesions suggest that the AFB tend to proliferate along and just above the fascial plane. Necrosis extends far beyond the limits of spread of AFB.

### Metastatic Disease

Potentially, *M. ulcerans* may enter the lymphatic system or bloodstream from any form of BU; however, it probably occurs more frequently with disseminated forms. Although clinical lymphadenopathy is not a feature of BU, local and regional lymph nodes reveal invasion of the afferent lymphatic vessels and cortical sinuses, often with extension into the medullary areas with necrosis. Targets for metastatic spread seem to be limited to skin and bone. Osteomyelitis, either contiguous (osteitis; Fig. 37-8) or metastatic, is seen in 10% to 15% of BU patients (Fig. 37-9).<sup>44-46</sup> Hematogenous spread appears to involve the epiphyseal/metaphyseal level initially in the long bones of the limbs, but the bones of the hands and feet are likewise affected.<sup>38</sup> Sometimes the soft tissue surrounding a bone is damaged to the extent that the bone becomes infarcted. Severe deformity and amputations are common sequelae of bone involvement. Microscopically, there is coagulation necrosis of the bone marrow and destruction of the trabeculae of the cancellous area of bones.

### PATHOGENESIS AND IMMUNITY

The pathogenesis of early *M. ulcerans* infection is related closely to at least two known properties of the etiologic agent: optimal growth at 30° to 33°C and elaboration of

**FIGURE 37-8** Radiograph shows contiguous osteomyelitis of the phalanges and metatarsal bones directly under a major ulcer of *M. ulcerans* disease on the dorsum of the foot.

a potent toxin.<sup>22</sup> Temperature requirement favors onset of lesions in skin. Toxin destroys tissue, providing a nutrient medium for bacillary proliferation and separating the organism from contact with immunocompetent cells. In vitro, the toxin is also directly immunosuppressive to both B and T cells.<sup>11</sup> Variations in clinical and histopathologic presentations of BU suggest that some individuals have innate resistance, some develop resistance early and others late, and a few seem to be totally anergic.

The skin test reagent “burulin” is a purified sonicate of cultured *M. ulcerans*. Intracutaneous inoculation of this reagent reveals that most BU patients do not show a delayed-type hypersensitivity response to *M. ulcerans* components early in the infection but do mount a cell-mediated response as healing begins.<sup>47</sup> This correlates well with the histopathologic appearance of delayed-type hypersensitivity granulomas in older lesions as they begin to heal. Presumably, the immunosuppressive effect on T cells, previously noted, and the immunologically isolated status of BU lesions resulting from the local necrosis limit the sensitization of immunocompetent cells in

**FIGURE 37-9** Amputations resulting from metastatic spread to bone of lower extremities. There is also spread to both wrists in this 13-year-old girl in Benin.

early and advancing stages of the disease.<sup>11</sup> The ultimate effect is T cell anergy, which prevents the development of the Th1 cellular response. Eventually there is sufficient immunostimulation by antigens of *M. ulcerans* to promote proliferation of peripheral blood mononuclear cells and production of  $\gamma$ -interferon to facilitate a Th1-type granulomatous response.<sup>12,46,48,49</sup> Sera from patients show humoral antibodies to soluble *M. ulcerans* antigens; however, their importance in pathogenesis and usefulness for diagnosis have not been defined.<sup>50</sup> Following the granulomatous stage, lesions heal by scarring.

Data on coinfection of BU and HIV are insufficient to establish increased susceptibility of patients with HIV/AIDS to BU. However, anecdotal observations suggest that BU disease is more aggressive in HIV-infected patients.<sup>51</sup>

## DIAGNOSIS

The experienced observer in endemic areas usually can make an accurate clinical diagnosis.<sup>52,53</sup> In ulcerated lesions, Ziehl-Neelsen stains of smears of exudates from the undermined edge often reveal clusters of extracellular AFB (Fig. 37-10). The same material, after decontamination, may be used for culture on Löwenstein-Jensen or other suitable mycobacterial media. Incubation temperature must be 30° to 32°C. Transport media may be employed if stains and cultures cannot be performed locally. Molecular biologic analysis of exudates or biopsy specimens using PCR techniques are available for the identification of *M. ulcerans*.<sup>16,54,55</sup>

Specimens for histopathologic analysis should come from the edge of the ulcer and include all levels down to and including the fascia. In nonulcerative disease (plaque or edematous), specimens should be taken from the presumed center of the lesion. Ellipses of tissue are diagnostically more productive than punch biopsy specimens. The differential diagnosis is extensive. In specimens studied at the Armed Forces Institute of Pathology (AFIP), where the primary clinical diagnosis was BU, the authors noted the following histopathologic diagnoses:

- Infections: staphylococcal abscess, tropical phagedenic ulcer, tuberculosis, atypical mycobacterioses (other

than *M. ulcerans*), Majocchi's granuloma, epididymitis, phycomycosis, phaeohyphomycosis, African histoplasmosis, filariasis, and leishmaniasis.

- Neoplasias: squamous and basal cell carcinomas, Kaposi's sarcoma, lymphoma, osteosarcoma, and a large variety of benign tumors of the skin such as fibromas and lipomas.
- Miscellaneous lesions: stasis ulcer, calcinosis cutis, epidermal cyst, gouty tophus, and foreign body granuloma.

## TREATMENT AND PROGNOSIS

A number of therapeutic drug trials are under study and some are promising, but none has had sufficient evaluation to permit recommendation. Excisional surgery remains the recommended therapy (Figs. 37-11 and 37-12). To inhibit metastatic spread, surgeons should prescribe antibiotic therapy before surgery and continue this therapy postoperatively for 2 to 3 weeks. Rifampin and clarithromycin combined is the most frequently used regimen.

Papules and nonulcerated nodules are widely excised and usually closed primarily.<sup>56</sup> This procedure is usually curative.<sup>57</sup>

Plaques and edematous disease are excised widely down to or through the fascia if necrotic. Any involved muscle should be excised. Determining the limits of lateral extension of disease is often difficult. Experienced surgeons may be able to determine these limits by palpation, but exploratory incisions and blunt dissections are useful to establish the lines of excision.<sup>44</sup> Marginal recurrences are frequent and must be further excised. Sometimes the involvement of skin is so extensive (e.g., loss of 75% of the skin of the trunk) that the very insult of the surgery is life-threatening. Split-skin autografting is usually performed after sufficient granulation tissue has developed. Small ulcers may be excised and closed primarily.

**FIGURE 37-10** Ziehl-Neelsen-stained smear of exudates from an ulcerated lesion of Buruli ulcer (×80). Acid-fast bacilli are consistently extracellular.

**FIGURE 37-11** Excised edematous lesion in a 9-year-old girl in Togo. Pockets of active disease are recurring in the borders.

**FIGURE 37-12** Patient in Figure 37-11 seen 5 years after complete excision and autologous split-skin grafting.

Large ulcers are excised using the principles described previously to determine the extent of excision. Postoperative care, especially physiotherapy, is essential for the prevention of contractures (Fig. 37-13). It is most important that the skin graft eventually covers the lesion completely because actinic radiation is strong in most endemic areas, resulting in cancers in nonpigmented surfaces. Bone lesions should be managed by specialists; however, management of bone lesions is outlined in a WHO manual.<sup>52</sup> Heat therapy without surgical excision is successful for appropriate lesions but must be applied assiduously, keeping the base of ulcers at 40°C by fully controlled heating jackets.<sup>58</sup> Open heat-cradles seldom meet the requirement.

**FIGURE 37-13** Frozen elbow from contracture scarring of a large, healed Buruli ulcer in a Ghanaian girl.

**FIGURE 37-14** Patient in Congo who lost an eye from a major ulcerative lesion of Buruli ulcer.

Prognosis is unpredictable. Surgically managed early small lesions have an excellent prognosis. However, any lesion may recur locally or spread metastatically after initial therapy, threatening the loss of significant tissue, and increasing the danger of cosmetic and disabling deformities and amputations.<sup>59</sup> Secondary septicemia, tetanus, and gas gangrene sometimes are fatal. Without initial appropriate treatment, patients are likely to become severely disabled, increasing the stigma of the disease (Fig. 37-14). These patients are prone to developing psychosocial problems and become a socioeconomic burden to the community and the health-care delivery system.<sup>4,60</sup>

## PREVENTION

In tropical rural settings where BU is endemic and scantily dressed children work and play, protection against contamination of the skin is virtually impossible. Although wearing long trousers reduces rates of infection, achieving this measure is not feasible.<sup>24</sup> Protected water supplies in villages reduces exposure to *M. ulcerans*—contaminated sources, but in most endemic countries, providing wells is not a priority. Thus, environmentally oriented plans for the control of BU are not likely to succeed, leaving vaccination programs the only viable alternative.

Vaccination with a single BCG inoculation protects against BU, but the effect against infection wanes after 6 to 12 months.<sup>61,62</sup> Nevertheless, the longstanding policy of neonatal vaccination with BCG, intended to prevent disseminated tuberculosis, does reduce the rate of osteomyelitis in BU-infected patients.<sup>46</sup> Because repeated BCG vaccination provides long-lasting protection against leprosy, plans are under way to test this approach for the control of BU.<sup>63</sup> Subunit vaccines based on virulence factors or antigens of *M. ulcerans* are being studied.<sup>64</sup>

# Leprosy

WAYNE M. MEYERS

## INTRODUCTION

Leprosy is a chronic infection by *Mycobacterium leprae*, affecting mainly the cooler body areas: skin, upper respiratory passages, anterior segments of eyes, superficial segments of peripheral nerves, and testes. The traditional, pervasive, social stigma attached to leprosy may be traced to the disfigurement, deformity, mutilations, and blindness related to damage to these tissues. In cultures influenced by Judeo-Christian orthodoxy, the ostracism leprosy patients suffer is frequently severe and, in part, attributable to what is called leprosy in the Old Testament.<sup>1</sup> The Hebrew word *tsara'ath* was translated *lepra* in the Septuagint, the first Greek version of the Old Testament (third century BC). Subsequent Latin and English translations of the Bible used *lepra* and *leprosy*, respectively. The original Hebrew word denoted a group of diseases, none of which had recognizable clinical features of leprosy, and referred generally to ceremonial uncleanness.<sup>2</sup> Cultures never influenced by Judaic laws, however, frequently had or have similar attitudes toward leprosy—for example, the Chinese as early as the eighth century BC.<sup>3</sup> To ameliorate the stigma of the disease, the International Leprosy Association in 1948 abandoned the word “leper” for “leprosy patient.”<sup>4</sup> Today, the term “Hansen’s disease” is a frequent synonym for leprosy.<sup>5</sup> Prevention of disability and conservation of cosmetic integrity are of utmost importance to preserve productivity and social acceptance.

## AGENT

*M. leprae*, measuring  $0.5\ \mu\text{m} \times 4.0$  to  $7.0\ \mu\text{m}$ , is an acid-fast bacillus (AFB) in the order Actinomycetales and family Mycobacteriaceae. The Ziehl–Neelsen method stains *M. leprae* in smears, but in tissue sections the Fite–Faraco method is optimal. Acid-fastness is related to mycolic acid in the cell wall.<sup>6</sup> Staining properties of *M. leprae* in skin smears or biopsy specimens are important in the rapid assessment of the therapeutic efficacy of antileprotics. Viable organisms stain solidly, and as they degenerate, stain irregularly, then become granular, and eventually non-acid-fast. Persistence of bacillary carcasses in tissues or in smears can be established by silver staining techniques.<sup>7</sup> In multibacillary patients such carcasses may remain in macrophages for several years after the leprosy bacilli have lost acid-fastness.

In 1873, in Norway, Hansen proposed that the bacillary bodies he saw in unstained tissue fluids from lepromatous nodules were the cause of leprosy. This was the first mycobacterium and the first etiologic agent of a chronic disease identified in humans. The leprosy bacillus is apparently an

obligate intracellular parasite; however, investigators occasionally report in vitro cultivation in cell-free media. All such claims remain unsubstantiated.<sup>8</sup> Because *M. leprae* is, as yet, noncultivable, identification of candidate organisms as *M. leprae* depends on ancillary criteria, as follows: (1) fails to grow on routine mycobacteriologic media; (2) infects the foot pads of mice in a manner consistent with that of *M. leprae*<sup>9</sup>; (3) acid-fastness is abolished by exposure to pyridine<sup>10</sup>; (4) invades nerves in humans or experimental hosts; (5) suspensions of killed bacilli produce a characteristic pattern (“lepromin reaction”) when injected into the skin of leprosy patients with each of the various clinical forms<sup>11</sup>; (6) produces phenolic glycolipid–1 (PGL-1), a presumed species-specific antigen<sup>12</sup>; and (7) contains species-specific DNA sequences.<sup>13</sup> Cell walls of *M. leprae* contain arabinogalactan, mycolates, peptidoglycan, and protein.<sup>14</sup> Constituents of the cell wall appear to play a significant role in the *M. leprae*–host cell interaction, both in protecting the parasite and in stimulating immune responses.<sup>15–18</sup> The *M. leprae* genome contains 3,268,203 base pairs with a G + C % of 57.79. Only 1604, or 49.5%, of the genes encode proteins, compared with 3959, or 90.8%, for *Mycobacterium tuberculosis*. This represents a massive deficit of metabolic capabilities for *M. leprae* that probably explains why it has not been cultivated in vitro.<sup>19</sup> The assumed gene decay may be related to the long multiplication time of 13 days for *M. leprae*, as observed in the foot pads of immunologically intact mice, and to the normally long incubation periods of leprosy. In less resistant hosts such as nude mice, generation times may be as short as 26 hours,<sup>20</sup> approaching that of 18 hours for *M. tuberculosis*. This may help explain the short incubation periods in some highly susceptible infants under 1 year of age.<sup>21</sup> Preferential localization of lesions of leprosy to cooler body locations,<sup>22</sup> selective growth in foot pads of normal mice, and the marked susceptibility of armadillos (body temperature 32 to 35°C) suggest that the optimal growth temperature for *M. leprae* is lower than 37°C.<sup>23</sup>

## EPIDEMIOLOGY

Leprosy and its transmission do not require a tropical environment. Historically, the disease has afflicted people in nearly every part of the world, including countries traversed by the Arctic Circle. Today the higher prevalences in the tropics are best attributable to socioeconomic factors. In 1995 the World Health Organization (WHO) estimated that there were 1.83 million people in the world with active leprosy.<sup>24</sup> This represents a marked reduction in the global prevalence of leprosy in the several previous decades (12 to 15 million); however, the annual reported incidence of new patients (approximately 700,000) remains unchanged. A considerable portion of the reduction in total numbers of patients may be artificial and attributable to the redefinition of a case of leprosy. Today only individuals who receive chemotherapy for leprosy are counted as cases. Prevalence rates vary: Of all patients, southern Asia has 75% (India alone, 65%); Africa, 12%; and the Americas, 8%. In the United States there are an estimated 6000 people with a history of leprosy, with 133 new patients reported in 2003, 26 of whom were born in the United States.<sup>25</sup>

Infected humans are the most common source of leprosy; however, nonhuman reservoirs are well known. Naturally acquired leprosy was first detected in armadillos in Louisiana

in 1974 and infects up to one-half of the armadillos in some foci.<sup>26,27</sup> Similarly, indigenous leprosy has been detected in chimpanzees and monkeys in West Africa and elsewhere.<sup>28–30</sup> Humans may acquire leprosy from wild infected armadillos,<sup>31,32</sup> and possibly from other zoonotic sources in other geographic areas. There is no evidence for transmission of leprosy by insects or any other vector.

Prevalence of disease seldom exceeds 5% in most large populations. In adults, the male-to-female ratio is 2 to 3:1, but in children, it is 1 to 1. Specific immunologic parameters in subjects in Ethiopia suggest that occupational contacts, for example, health care workers, have the highest sensitization rates to *M. leprae* (58%), followed by household contacts (47%), and noncontacts in endemic areas (29%).<sup>33</sup> In most populations living in endemic areas, 5% to 10% of infected persons develop progressive clinical disease.<sup>34</sup> Children usually constitute 20% to 30% of all cases detected.<sup>35</sup> The role of genetic factors is unclear: In some ethnic groups, certain HLA-DR types are associated with the particular type of leprosy, but not necessarily with susceptibility.<sup>36,37</sup>

Lower prevalences of leprosy correlate directly with the availability of adequate housing and level of living standards. This is perhaps the best explanation for the disappearance of leprosy from northern Europe beginning just after the Middle Ages, and explains the tendency for leprosy to prevail today in the underprivileged areas of the world, primarily the tropics. Other public health factors common to the tropics may influence the prevalence of leprosy. For example, there is a markedly increased frequency of intestinal nematode infections in lepromatous leprosy in Brazil and probably in most tropical climates. Diniz and colleagues attribute this to a modulation of the host immune response by these parasites: down-regulation of the Th1 and up-regulation of the Th2 responses.<sup>38</sup>

## DISEASE

Leprosy is a paradigm for the understanding of the range of clinical and pathologic interactions between variable host responses and a bacterium with relatively stable virulence. The immune response determines the position of a patient in the classic spectrum of disease forms described in Table 38-1, which reflects the popular Ridley–Jopling classification.<sup>39</sup> The WHO classification of leprosy for field workers is assumed to be based on the bacterial burden in tissues: *paucibacillary* (PB), patients with skin smears negative for AFB, or five or fewer cutaneous lesions; and *multibacillary* (MB), those with skin smears positive for AFB, or more than five lesions.<sup>40</sup> Some versions of the WHO classification suggest that skin smears be excluded. Observations by the author indicate that a system based only on number of lesions is prone to errors in classification that can be moderated by the use of skin smears for AFB, or by histopathologic analysis.

The immunologic capability of an individual, including patients, in relation to *M. leprae*, is assessed by the intra-dermal inoculation of 0.1 mL of *lepromin*, a suspension of heat-killed *M. leprae* ( $1.6 \times 10^8$  organisms per milliliter), obtained today from experimentally infected armadillos.<sup>11</sup> The response is evaluated by measuring the diameter of induration at the injection site 3 to 4 weeks postinoculation (Mitsuda reaction).<sup>41</sup> Because high percentages of all normal populations react,<sup>42</sup> this skin test is never diagnostic but is useful in the classification of disease: Tuberculoid leprosy and borderline tuberculoid leprosy patients are strongly positive (>5 mm); lepromatous leprosy, weakly or nonreactive (0 to 2 mm); and borderline lepromatous and midborderline have intermediate reactions (3 to 5 mm; see Table 38-1).

**Table 38-1 Clinical and Histopathologic Classification of Leprosy**

Clinical Features	Histopathologic Features
<b>Tuberculoid (TT)</b> Few well-defined anesthetic macules or plaques; neural involvement common	Granulomas with or without giant cells; rare bacilli; nerves damaged; no subepidermal freezezone
<b>Borderline Forms</b>	
<b>Borderline tuberculoid (BT)</b> More lesions, borders less distinct; neural involvement common	Similar to TT but with occasional bacilli, usually in nerves; subepidermal freezezone
<b>Midborderline (BB)</b> More lesions than BT, borders vague; neural involvement common	Epithelioid cells and histiocytes; focal lymphocytes; increased cellularity of nerves; bacilli readily found, mostly in nerves; subepidermal freezezone
<b>Borderline lepromatous (BL)</b> Numerous lesions, borders vague; less neural damage than in BB	Histiocytes, few epithelioid cells, some foamy cells; bacilli plentiful in nerves and histiocytes; subepidermal freezezone
<b>Lepromatous (LL)</b> Multiple macules, nodules, or diffuse infiltrations; symmetrically distributed neural lesions develop late	Foamy histiocytes with large numbers of bacilli; few lymphocytes; numerous bacilli in nerves; minimal intraneural cellular infiltration; subepidermal freezezone
<b>Indeterminate (I)</b> Vaguely defined, hypopigmented, or erythematous macules	Small lymphocytic infiltrates around nerves and appendages; rare bacilli, usually in nerves

Based on Ridley DS, Jopling WH: Classification of leprosy according to immunity: a five-group system. *Int J Lepr* 34:255, 1966.

**FIGURE 38-1** Indeterminate leprosy (arrow) on the leg of an Indian patient. The lesion is hypopigmented with vague borders.

Modifications of this test using a high concentration of leprosy bacilli show that lepromatous patients cannot clear *M. leprae* from the reaction site, whereas tuberculoid patients destroy the bacilli efficiently.<sup>43</sup> Thus, survival and multiplication of the etiologic agents in macrophages determine the form of leprosy: If macrophages destroy *M. leprae* rapidly, minimal or no lesions develop, but if macrophages do not control multiplication of *M. leprae*, severe disseminated disease follows. While there is considerable evidence that the level of cell-mediated immunity to *M. leprae* determines the progress of disease, the precise mechanisms are poorly defined. In lepromatous patients there may be anergy to a variety of antigens, but most strikingly and most consistently to those of *M. leprae*.<sup>44</sup>

### Indeterminate Leprosy

Indeterminate leprosy (I) is usually the earliest lesion and presents as poorly defined macules, mildly hypopigmented in dark skin and slightly erythematous in lighter skin (Fig. 38-1). Texture, the amount of hair, sensation, and sweating in the

**FIGURE 38-2** Indeterminate leprosy showing infiltration of a few lymphocytes around nerves and vessels in the lower dermis. Nerves are intact.

**FIGURE 38-3** Indeterminate leprosy. Note the single acid-fast bacillus (arrow) in a nerve twig of a parallel Fite-Faraco-stained section of lesion shown in Figure 38-2.

lesion are, at most, only slightly changed. Histopathologically, there are a few lymphocytes around neurovascular bundles (Fig. 38-2). These changes are nonspecific unless AFB are found in nerves, arrectores pilorum muscles, or in the subepidermal area (Fig. 38-3).<sup>45</sup> Diagnosis of indeterminate lesions often requires close cooperation between the histopathologist and clinician. Lesions may self-heal, remain unchanged for long periods, or progress to other forms of leprosy.

### Tuberculoid Leprosy

Tuberculoid leprosy (TT) patients have a single or few lesions, which may be macular or infiltrated. Borders are well defined and often finely papulated (Figs. 38-4 and 38-5). Sensation and sweating are impaired in lesions, and hair is frequently absent. Cutaneous nerves and peripheral nerve trunks are often enlarged in the region of lesions (Fig. 38-6). Sections of skin show epithelioid cell granulomas that invade nerves and often the epidermis (Fig. 38-7). AFB are rare and are found most consistently in nerves, papillary dermis, or arrectores pilorum muscles (Fig. 38-8).

**FIGURE 38-4** Early tuberculoid leprosy on the cheek of an Angolan boy. The lesion is hypopigmented with well-defined papular borders and is mildly hypesthetic. Early lesions on the face often have only slight or no sensory changes.

**FIGURE 38-5** Tuberculoid leprosy. A Congolese patient with a single anesthetic lesion that developed over 13 years. Note healed atrophic repigmented center and active hypopigmented and infiltrated edge.

### Borderline Leprosy

Borderline leprosy has three major subgroups: borderline tuberculoid (BT; Fig. 38-9), midborderline (BB), and borderline lepromatous (BL). This area of the spectrum is unstable, especially BB. BT lesions resemble those of TT but often are more numerous, and definition of their margins is less distinct. In BL there are widespread plaques and nodules. Histopathologically, the quality of the granulomas ranges from hyperergic with few AFB in BT, to nearly anergic with many AFB in histiocytes and nerves in BL. Damage to cutaneous and peripheral nerves develops early and is often severe and widespread (Fig. 38-10). Reversal reactions (type 1) are common, with resulting neuropathic changes, especially in the hands, feet, and face.

### Lepromatous Leprosy

Lepromatous leprosy (LL) infiltrates nearly the entire skin, but the cellular exudates are heaviest in the cooler areas, such as the ears, the central portion of the face, and the extensor surfaces of the thighs and forearms (Fig. 38-11). Physical examination may easily miss the subtle macules of early LL.

**FIGURE 38-6** Thickened great auricular nerve in tuberculoid leprosy. The healing lesion of leprosy is barely visible anterior to the ear.

**FIGURE 38-7** Tuberculoid leprosy. Granulomas composed of epithelioid cells, giant cells, and lymphocytes replace the dermis and invade the epidermis.

Damage to nerves develops slowly but relentlessly. There is insensitivity of hands and feet and loss of some body hair (e.g., eyebrows) at later stages. Other areas involved are the upper respiratory tract from the nasal mucosa to the larynx, the eye, lymph nodes, and testes. Sterility and gynecomastia may follow leprous orchitis. Histopathologically, macrophages densely infiltrate the dermis but leave a subepidermal clear zone (Fig. 38-12). Nerves are rather well preserved until late. AFB abound in nerves, macrophages, blood vessel walls, and arrectores pilorum muscles, with many AFB in clumps and globi (Fig. 38-13).

### Other Manifestations of Leprosy

Occasionally in LL, especially in relapsing patients, elevated firm nodules appear in the skin. Histologically, the

**FIGURE 38-8** Damaged dermal nerve in lesion of tuberculoid leprosy. The nerve contains two acid-fast bacilli (arrow).

**FIGURE 38-9** Borderline tuberculoid leprosy in a Congolese patient undergoing a mild reversal reaction. The multiple lesions are sharply delineated, infiltrated, and erythematous. Peripheral nerve trunks were painful, enlarged, and tender.

macrophages resemble fibrocytes arranged in whorls, as in dermatofibromas, and contain numerous AFB. These lesions are called *histoid* leprosy.<sup>46</sup>

In patients of Latin American ancestry, particularly Mexicans, there is a highly anergic form of LL called *Lucio's leprosy*. Infiltration of skin is so diffuse that the diagnosis is often missed. In advanced stages, *Lucio's phenomenon* may develop, characterized by obstructive vasculitis causing dermal infarcts and ulcers (Fig. 38-14), often involving massive areas of the skin.

Occasionally *pure neural leprosy* affects peripheral nerves in the absence of cutaneous lesions. Biopsy specimens of nerves may show any form of leprosy, but most are borderline disease. On presentation patients have one or more painful enlarged peripheral nerves accompanied by sensory loss, paresis, or muscular wasting.

## Reactions

The course of leprosy is often punctuated by acute reactional episodes. Reactions are classified into two categories:

**FIGURE 38-10** Mutilated and deformed insensitive hands of a Pakistani woman due to multiple peripheral neuropathies of borderline leprosy. Note flattening of palms from loss of thenar and hypothenar eminences.

**FIGURE 38-11** Lepromatous leprosy showing heaviest infiltrations of skin over the central portion of the face. The eyebrows are thinned.

type 1, or reversal reactions (Fig. 38-15), and type 2, or *erythema nodosum leprosum* (ENL; Fig. 38-16).

Reversal reactions are most frequent in borderline leprosy and represent an episodic upgrading of cell-mediated immunity. Existing cutaneous lesions become swollen and erythematous. Neuritis is common and is responsible for much of the sensory loss and deformities of borderline leprosy. By repeated reversal reactions, borderline lesions may gradually upgrade toward tuberculoid disease. Today, with defined short-term therapeutic regimens for treatment, both the clinician and the pathologist are confronted with the problem of differentiating relapsing leprosy from upgrading reversal reactions. The following criteria have been formulated<sup>47,48</sup>: *relapse*—increased number of lesions, skin smear positive for AFB (BB and BL patients), tissue reaction inconsistent with reversal reaction, and favorable response to antileprosy therapy; *reversal reaction*—exacerbation of sites of previous lesions, skin smear negative, tissue reaction suggesting reversal reaction, and rapid response to anti-inflammatory therapy (e.g., corticosteroids).

**FIGURE 38-12** Lepromatous leprosy showing subepidermal clear zone and replacement of the dermis by vacuolated macrophages.

**FIGURE 38-13** High-power magnification of a Fite-Faraco-stained section of Figure 38-12 showing massive numbers of acid-fast bacilli in macrophages.

Lepromin-positive patients with IgM antibodies to PGL-1 are at greatest risk of reversal reactions, suggesting participation of both humoral and cell-mediated components.<sup>49</sup> Sensitized T lymphocytes proliferate in reversal reactions, releasing cytokines that call in and activate macrophages.<sup>50</sup> Tissue reaction shows edema, increased numbers of lymphocytes, epithelioid cells, and giant cells. This is the only instance where hyperergic lesions of leprosy may show necrosis in granulomas and dermal nerves. Increased TNF- $\alpha$  may provoke this necrosis.<sup>51</sup>

Erythema nodosum leprosum (ENL) develops in approximately half of all lepromatous patients. Clinically, there is rapid onset of tender subcutaneous nodules, often accompanied by fever, synovitis, and iridocyclitis. ENL lesions resemble the Arthus phenomenon and probably are related to immunocomplexes that form locally by the release of antigens of *M. leprae* that combine with circulating antibody and probably modulate the T-lymphocyte populations in situ. There are, for example, increased numbers of T helper cells within lesions,<sup>52</sup> and TNF- $\alpha$  is increased.<sup>53</sup> Histopathologically, neutrophils usually infiltrate the lesion, often accompanied by vasculitis and ulceration.

**FIGURE 38-14** Lucio's lepromatous leprosy in a Mexican patient. Punched-out irregular ulcers are at sites with infarcts caused by obliterative vasculitis of dermal and subcutaneous vessels.

**FIGURE 38-15** Early reversal reaction in a Congolese boy with a borderline tuberculoid lesion on the face. Note the swollen left side of the face with slight ipsilateral facial palsy. Corticosteroid therapy rapidly reduced the swelling and restored full facial nerve function.

Elevation of serum amyloid A and C-reactive protein may help establish the diagnosis in atypical lesions.<sup>54</sup> Secondary amyloidosis in LL is seen most frequently in patients with chronic ENL.

## PATHOGENESIS AND IMMUNITY

In humans, direct skin-to-skin contact or fomites may transmit leprosy,<sup>55</sup> but the nasorespiratory route is believed to be most common.<sup>56</sup> Secretions from the nasal mucosa of untreated lepromatous patients contain large numbers of viable leprosy bacilli.<sup>57</sup> *M. leprae* bacilli, after drying in the shade, in India, remain viable for up to 5 months, and in wet soil for 46 days.<sup>58</sup> Thus, the leprosy bacilli could be carried in aerosols and contaminate the nasal mucosa, perhaps first binding to fibronectin and then to fibronectin receptors on mucosal cells.<sup>59</sup> Transmission through mother's milk or transplacental infection is plausible. Breast tissue and mother's milk of multibacillary patients may contain large numbers of *M. leprae*, putting their nursing infants at risk.<sup>60</sup> There is increasing evidence for placental transmission of leprosy. Cord blood contains *M. leprae*-specific IgA and IgM antibodies,

**FIGURE 38-16** Erythema nodosum leprosum in a Filipino patient with lepromatous leprosy. Some of the numerous tender, soft nodules will rupture and discharge pus.

and titers of these antibodies rise in some infants of lepromatous mothers over 3 to 24 months after birth.<sup>61,62</sup> Leprosy in infants under 1 year of age is well known. In one series of 49 such infants, the youngest patient was 2 months old at diagnosis,<sup>21</sup> and the mother had clinical leprosy in only about half of these infants. This implies that during gestation the mother had a transient subclinical *M. leprae* bacteremia.

Bacteremia is common in multibacillary leprosy and in up to 15% of paucibacillary patients.<sup>63,64</sup> Invasion and multiplication of *M. leprae* in dermal lymphatic and vascular endothelial cells probably plays a major role in the hematogenous spread of the bacillus.<sup>65,66</sup> Scollard and associates have demonstrated that *M. leprae* invades peripheral nerves via the blood (and possibly lymphatic) vessels of the perineurium, gaining access to the endoneurial compartment.<sup>67</sup> Infection of endothelial cells by *M. leprae* may lead to ischemia of nerve, contributing to peripheral neuritis. The Schwann cell of peripheral nerves is the classic target for *M. leprae*. Rambukkana and coworkers have shown that laminin-2 in the basal lamina of the Schwann cell–axon unit binds to *M. leprae*, and ultimately that the  $\alpha$ -dystroglycan receptor of the Schwann cells binds with laminin-2.<sup>68</sup> This may be one mechanism by which Schwann cells become infected.

Disturbances in the modulation of T lymphocyte–macrophage function in the different forms of leprosy are well known. Total numbers of circulating T lymphocytes may be decreased in advanced lepromatous disease, but T-cell subset ratio variations are not consistent.<sup>69</sup> In lesions, however, T helper (CD4+) cells predominate in tuberculoid leprosy, and T suppressor (CD8+) lymphocytes predominate in lepromatous disease.<sup>70,71</sup> Increased suppressor cell activity in lepromatous leprosy may be induced by lepromin<sup>72</sup> or PGL-1,<sup>73</sup> and may in part be related to infiltration of paracortical areas of lymph nodes by *M. leprae*–laden macrophages.<sup>74</sup>

Much is known about the immunologic perturbations in leprosy, which have been extensively reviewed.<sup>75</sup> Protective mechanisms against leprosy, the contribution of the T-cell subsets, cytokine networks, and macrophage bactericidal mechanisms, for example, remain unresolved.<sup>76</sup>

Classically, CD4+ T lymphocytes recognize specific antigens when associated with HLA and produce interferon- $\gamma$  (IFN- $\gamma$ ), which activates macrophages. Macrophages from lepromatous patients, once activated by cytokines, have the capacity to kill and clear *M. leprae*.<sup>77</sup> Production of interleukin-2 (IL-2) and IFN- $\gamma$ , however, is deficient in lepromatous patients. This suppression may represent an effect of CD8+ T suppressor cells by reducing proliferation of sensitized T cells and inhibiting activation of macrophages. IL-2 restores proliferation of lymphocytes and IFN- $\gamma$  production in response to specific stimulation.<sup>75,78,79</sup> Injection of IL-2 and IFN- $\gamma$  into lepromatous lesions increases the influx of CD4+ T cells, activating macrophages and reducing bacillary load.<sup>80,81</sup> These cytokines may have therapeutic value but do provoke tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), which may be associated with reversal reactions in skin and peripheral nerves.<sup>82</sup>

The immune response, as it may relate to the spectrum of disease forms in leprosy, may be summarized as follows: In tuberculoid leprosy the response is that of Th1-like T cells, and in lepromatous leprosy there is a Th2 response producing cytokines IL-4 and IL-10.<sup>83</sup> These different immunologic responses of the host determine, in large measure, the different

clinical and histopathologic forms in the spectrum of leprosy (see Table 38-1).

## DIAGNOSIS

The cardinal signs of leprosy are hypoesthetic lesions of the skin, enlarged peripheral nerves, and AFB in skin smears. In the absence of another clear diagnosis, any one of these observations suggests leprosy. Delay in diagnosis is often prolonged following the first visit to a physician for leprosy-related symptoms; in the United States, this period averages 1 to 1.5 years. Such delay may result in irreversible sequelae.

## Physical Examination

History of contact or residence in endemic areas raises suspicion of leprosy in a patient with chronic lesions of the skin. Experienced observers can often make the diagnosis clinically. Histopathologic evaluation is, however, strongly recommended for confirmation of the diagnosis and classification.

The entire skin surface should be examined. Vague changes are best seen in direct sunlight. Peripheral nerves are palpated for enlargement and tenderness. Cutaneous nerves in or near lesions may be enlarged. Unexplained damage to hands or feet, or any muscle weakness (e.g., clawhand or foot-drop) or sensory deficit strongly suggests peripheral neuropathy. Lepromatous patients may have a chronic stuffy nose.

Sensory changes in lesions are tested for light touch with a few fibers of cotton or calibrated nylon bristles, and for heat–cold discrimination by warm and cool water in test tubes. Sensory changes are the most important criterion for clinical diagnosis; thus, repeated testing is recommended in doubtful situations.

## Skin Smears

Skin smears are obtained from multiple sites (usually six to eight) and should include the edge of macules or plaques, nodules, both earlobes, and the nasal mucosa. Skin smears are made by squeezing a fold of skin between thumb and forefinger, and making a short shallow slit in the skin with a razor blade or scalpel. The instrument is then turned at a right angle to the slit, and the sides of the slit are scraped. The fluid thus obtained is spread on a slide over a circle approximately 1 cm in diameter, heat-fixed, and stained by the Ziehl–Neelsen method. Evaluation of the smears must be performed by experienced personnel to avoid misinterpretation (e.g., reagents may be contaminated with AFB).<sup>84</sup>

Serologic tests for the *M. leprae*–specific PGL-1 antigen and antibodies to PGL-1 are available.<sup>85–87</sup> Specificity is high, and most lepromatous patients are positive. Paucibacillary patients, however, are frequently nonreactive. Other serologic tests based on proteins of *M. leprae* are under study.<sup>88</sup> Multibacillary patients have PGL-1 antigen in serum and urine.<sup>89,90</sup> DNA technology is able to detect small numbers of *M. leprae* in tissue sections, skin, and nasal smears. Because of potential contamination in laboratories in endemic areas, all data from DNA findings must be interpreted carefully and correlated clinicopathologically.<sup>13,34,91</sup> Sera from lepromatous patients may give false-positive reactions for syphilis in cardiolipin-based assays.

## Histopathologic Studies

Biopsy specimens should be taken from the edges of lesions and should include the entire thickness of the skin and subcutaneous tissue. Occasionally, damaged nerves may appear only in the subcutaneous tissue. Punch biopsy specimens are most convenient, but should be as large as is cosmetically acceptable for the site chosen. The specimen should be fixed in 10% buffered formalin for routine evaluation. If DNA studies are anticipated, the specimen must be preserved in 70% ethyl alcohol.<sup>92</sup> To demonstrate *M. leprae* optimally in tissue sections, the Fite–Faraco method is essential.<sup>93</sup> A diagnosis of leprosy is made only when the evidence is convincing; “consistent with leprosy” must be avoided in histopathologic evaluations.

## Differential Diagnosis

Only a few of the extensive list of differential diagnoses can be given here; they are listed in three categories:

1. *Changes in pigmentation.* Superficial mycoses, scars, birthmarks, postinflammatory changes, and cutaneous filariasis (onchocerciasis and streptocerciasis)<sup>94</sup>
2. *Infiltrated lesions.* Leishmaniasis, lymphoma, granuloma annulare, granuloma multiforme (Mkar disease),<sup>95</sup> lupus erythematosus, psoriasis, pityriasis rosea, sarcoidosis, and neurofibromatosis
3. *Peripheral neuropathies.* Syringomyelia, lead toxicity, diabetes mellitus, primary amyloidosis, and familial hypertrophic neuropathy

## TREATMENT AND PROGNOSIS

Because of known drug-resistant strains of *M. leprae*, especially to dapsone and rifampin, monotherapy with any antileprotic is proscribed.<sup>96,97</sup> The type of antibacterial multidrug therapeutic (MDT) regimen employed is usually based on the WHO simplified classification of the disease, that is, PB or MB, and utilizes the WHO recommended combination of drugs,<sup>98–100</sup> as follows:

**Single lesion regimen:** Some clinicians treat patients who have only a single skin lesion with a single dose combination of rifampin 600 mg, ofloxacin 400 mg, and minocycline 100 mg. In the author's view, there are insufficient long-term follow-up data on efficacy to recommend the general use of this therapeutic approach. Such patients should be treated at least by the PB regimen.

**Paucibacillary regimen:** Rifampin 600 mg given once monthly under supervision, plus dapsone 100 mg/day for 6 months. Treatment is then discontinued.

**Multibacillary regimen:** Rifampin 600 mg and clofazimine 300 mg are given once monthly under supervision, plus dapsone 100 mg/day and clofazimine 50 mg/day for at least 12 months; however, some authorities recommend continuation of treatment for 24 months.<sup>83</sup> If hyperpigmentation of skin by clofazimine is not acceptable, prothionamide, ethionamide, or minocycline may be substituted.

Doses of the WHO regimens for children are given in Table 38-2.<sup>101</sup>

In the United States, the National Hansen's Disease Programs (NHDP) recommends the following regimens<sup>102</sup>:

**For PB disease:** dapsone 100 mg daily plus rifampin 600 mg daily, for 12 months

**For MB disease:** dapsone 100 mg daily plus rifampin 600 mg daily and clofazimine 50 mg daily, for 24 months

*Note:* The NHDP recommends that rifampin be given monthly (600 mg) if the patient is currently taking corticosteroids.

Apart from the increasing prevalence of drug resistance of strains of *M. leprae*, multidrug regimens are recommended for their potential for elimination of “persisting” organisms. Persisting *M. leprae* organisms are those leprosy bacilli that are susceptible to the drugs used in therapy, but which can still be identified in small numbers from patients who respond satisfactorily clinically. Such organisms may be responsible for relapses following therapy. Relapse rates following MDT are low but acceptable by most authorities—less than 1% in one large series of patients.<sup>103</sup> A follow-up, however, of 5368 patients for a mean of 10.8 years by Cellona and colleagues showed an absolute relapse rate of 3%; but of particular concern were rates as high as 13% in some subsets of patients.<sup>104</sup> In most populations of patients, relapses are highest in PB patients, suggesting that some patients are wrongly classified. In the experience of histopathologists, clinicians using the WHO system often misclassify MB patients and place them in the PB category. Thus, such patients are apt to be undertreated. There are anecdotal reports of highly bacilliferous patients with relapse rates of up to 20%.<sup>105</sup> Although results of the WHO MDT appear excellent, long-term follow-up is essential.<sup>106</sup> Resistance to all of the drugs in the WHO MDT regimen has been occasionally reported.<sup>107</sup> In view of these various reports of relapse rates, recommendations for MDT regimens should be given regular reappraisal, especially regarding kinds and dosage of drugs and duration of therapy, with special emphasis on long-term follow-up.

Several other potent antileprosy drugs and combinations are under clinical trial and may eventually be included in multidrug regimens. Among these are the fluoroquinolones pefloxacin and ofloxacin, the macrolide clarithromycin, and the tetracycline minocycline.<sup>108–112</sup>

Efficacy of chemotherapy in lepromatous patients can be assessed by clinical progress and the staining property of *M. leprae* in skin smears or biopsy specimens. The response of tuberculoid and borderline patients is best measured by the clinical response and histopathologic evaluation. Viability of *M. leprae* in patients can be determined by mouse foot pad inoculation or by a variety of other, more rapid metabolic assays.<sup>113</sup>

**Table 38-2 World Health Organization Regimens for Multidrug Therapy Regimen for Leprosy in Children**

Weight (kg)	Percentage of Adult Dose
15–30	50
30–45	75
>45	100

From Jopling WH: Handbook of Leprosy. London, Heinemann, 1984.

Care of insensitive hands and feet and correction of physical deformities are essential to the comprehensive treatment of the affected patient. This is an extensive topic, and the reader is directed to appropriate texts on the subject.<sup>114–116</sup>

## Therapy for Reactions

*Reactions in leprosy are considered a medical emergency. Appropriate treatment should be instituted immediately and the patient followed closely.*

## Reversal Reaction

If the reaction is accompanied by peripheral neuritis, the affected part is immobilized by a splint, and analgesics and corticosteroids given orally. Up to 80 mg of prednisone daily is given initially and tapered off over 2 to 3 months to a minimally effective level as long as neuritis persists. If long-term prednisone therapy is required, an alternate-day regimen may be attempted. Although suggested by some, the usefulness of clofazimine as an adjunct to corticosteroids in reversal reactions has not been established.<sup>117</sup> Antileprosy therapy is continued during treatment for reactions.

## Erythema Nodosum Leprosum

Because all MDT regimens for MB leprosy contain clofazimine, which has significant anti-inflammatory activity, severe ENL is encountered less frequently today. In milder forms of ENL, therapy may require only mild analgesics. Severe ENL requires more aggressive therapy, especially when there is iritis, neuritis, cutaneous ulceration, or orchitis. Thalidomide is the most active drug for ENL, and the initial dose is 100 mg three to four times daily.<sup>118</sup> This dosage is then tapered to the minimum effective level. Clofazimine may also be increased to up to 300 mg/day, but an effect is not usually observed until after use for 4 to 6 weeks. Thalidomide is prescribed only for males and nonfertile females, and some clinicians will administer the drug only to inpatients under direct supervision. Efficacy of thalidomide may depend in part on inhibition of TNF- $\alpha$  production, but other cytokines are probably also affected.<sup>75</sup> If thalidomide cannot be used, prednisone is given as for reversal reactions. Iridocyclitis is a serious complication; local corticosteroids must be added to systemic anti-inflammatory treatment and ophthalmologic consultation obtained.

## PREVENTION AND CONTROL

There are no recommendations for prevention of infection in endemic areas. Chemoprophylaxis of close contacts may be useful but is probably not appropriate for large populations.<sup>119,120</sup>

Current control programs are based on the principles that (1) the number of contagious patients is reduced by chemotherapy, and (2) the surveillance of contacts will detect early leprosy. Execution of these principles requires intensive programs in education of the public and training of medical personnel to diagnose leprosy and deliver treatment. A rapid low-cost test for PGL-1 detection offers promise for the identification of contacts of leprosy patients at risk and could be incorporated into control programs.<sup>121</sup> Skin tests specific for

leprosy would represent a marked advance in early diagnosis and are under study.<sup>122,123</sup> If such a skin test is considered successful, in view of the fact that many exposed individuals do not go on to develop disease, the ethical management of positive skin reactors without clinical findings must be resolved.

Effective vaccination offers the best approach to the elimination of leprosy infection in humans.<sup>124</sup> Initial evaluation in Venezuela of the WHO vaccine composed of heat-killed *M. leprae* plus bacille Calmette–Guérin (BCG) did not show protection against leprosy.<sup>125</sup> A single BCG vaccination gives varying levels of protection in different geographic areas. A study in Malawi, however, employing repeated BCG vaccinations gave an overall protection rate of 50% against leprosy, with 95% protection in children under 15 years of age.<sup>126</sup> Other trials of vaccines based on cultivable mycobacteria (*Mycobacterium w* and the ICRC bacillus) are in progress in India.<sup>127,128</sup> The development of potential vaccines based on subunit mycobacterial antigens are in the early planning stages.<sup>83</sup>

In contrast to the association of tuberculosis with human immunodeficiency virus (HIV), HIV infection may not be a significant risk factor for leprosy in most populations.<sup>129,130</sup> In some populations in Africa, HIV infection has an overall 2.2 relative risk for leprosy, and up to 23% of the multibacillary infections were HIV-infected.<sup>131</sup> Thus, the eventual effect of HIV infection on control of leprosy remains undetermined.

There is cautious optimism that rigorous application of the WHO MDT regimens will interrupt transmission of leprosy and diminish the incidence. The goal of WHO is to eliminate leprosy as a public health problem, that is, to achieve a prevalence of active leprosy of one patient or less per 10,000 population in all countries. Initially, the year 2000 was set as the time goal for achieving this level of elimination; however, this goal was not reached and has been extended to 2005, and programs that give special attention to the higher endemic foci have been established. To maintain patient confidence and provide more complete care, it should be mandatory that all such programs include resources for follow-up and management of the physical disabilities and social stigma of patients who have completed fixed-duration therapeutic regimens.<sup>83,132</sup> The integration of leprosy control operations into the general health care programs of most countries today makes this goal a formidable task.

## Anthrax

DAVID H. WALKER

### INTRODUCTION

*Bacillus anthracis* is a large ( $1 \times 3$  to  $10 \mu\text{m}$ ), gram-positive bacillus (Fig. 39-1) that resides as a  $1 \mu\text{m}$  spore in the soil and causes fatal disease in livestock, thereby again contaminating the soil.<sup>1-4</sup> Anthrax is a particular problem in tropical environments in Africa, Asia, South and Central America, and the Caribbean in locations where veterinary services are lacking and traditions and economic conditions lead to butchering and use of meat, hide, and wool from animals that die suddenly.<sup>5-8</sup> Anthrax has played an important role in the history of medicine. Presumably, human cases have occurred since the domestication of livestock, if not before, when hunters and gatherers came upon an infected wild herbivore soon before or after its demise. Cutaneous anthrax was described by Maret in 1752. Davaine in 1863 and 1864 reported that the disease was experimentally transmissible and that the same organisms were present in infected humans and animals. Subsequently both Koch and Pasteur employed *B. anthracis* in their studies in the 1870s, which established the concepts of infectious disease and immunity. By 1879, the cause of cutaneous and inhalational anthrax had been proved.

### AGENT

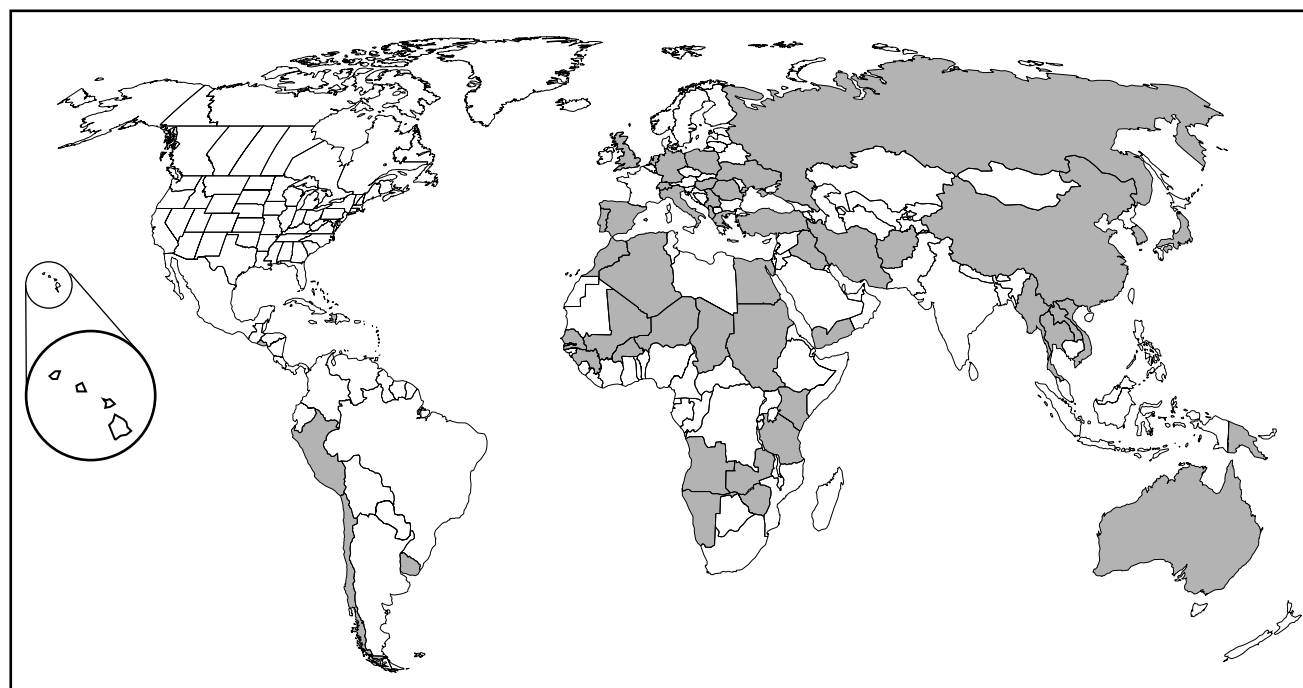

*Bacillus anthracis* has a 5.23 Mb genome encoding 5508 proteins.<sup>9</sup> Seven *gerA* family sensors recognize small molecules such as nutrients and ions leading to germination of the spore.<sup>10</sup> Two plasmids, pX01 and pX02, encode the toxins and capsule synthesis genes, the synthesis of which is controlled by *atxA* and *acpA* regulator genes.<sup>11</sup> Sporulation involves not only synthesis of the spore coats but also loading with components needed during early germination.<sup>10</sup> The very limited genetic diversity of *B. anthracis* suggests that it has spread as a clone throughout the world.

### EPIDEMIOLOGY

Domestic and wild herbivores, including sheep, goats, cattle, water buffalo, antelopes, elephants, giraffes, and zebras, are highly susceptible to fatal infection.<sup>12-14</sup> During periods of drought when grasses are scarce and short, herbivores ingest spore-contaminated soil along with the short vegetation. In other settings, it has been proposed that rainfall carries spores to low areas where evaporation deposits them in high quantities on the vegetation and the ground as well as in ponds where their persistence has been documented for as long as 18 years.<sup>15</sup> It has been postulated that water holes are sites of anthrax transmission because vultures contaminated with *B. anthracis* spores wash themselves there.<sup>13</sup> Carrion birds and mammalian predators, such as jackals, hyenas, and lions, are normally resistant to the disease. The vegetative bacilli form spores when they are exposed to the nutritionally deficient conditions outside the animal's body. Vegetative organisms remaining inside tissues at higher ambient temperatures are destroyed efficiently by putrefactive bacteria. Preterminal efflux of bloody, highly infected material from the animal's mouth, nose, and rectum is a major source of spores in the soil. Opening the carcass, whether for butchering meat, harvesting the hide, or necropsy, increases the quantity of spores in the environment. Predators and carrion birds accomplish

**FIGURE 39-1** Photomicrograph of gram-positive *Bacillus anthracis* in the soft tissue of a fatal case of septicemic cutaneous anthrax. (Brown-Hopps stain;  $\times 1600$ .) (Courtesy of Dr MJ Hale, The South African Institute for Medical Research.)

Countries with cases of human infection with *Bacillus anthracis*  
 ■ Global distribution

not only this result but also can transport anthrax organisms in contaminated parts of the carcass and in their own feces over substantial distances. Thus, the cycle of deposition of spores in the soil and their consumption by herbivores continues. The best example of the ability of spores to survive in the soil is the biological warfare experiments on Gruinard Island off the western coast of Scotland.<sup>3</sup> Explosive release of spores in 1942 and 1943 resulted in soil contamination that persisted until 1986 when extensive formaldehyde decontamination was successfully accomplished. Where anthrax in domestic animals has been a problem in the past, it may remain so unless effective preventive vaccination is implemented and maintained.

Humans become incidentally infected when contacting spores on dead animals or their meat, hides, hair, or wool. The most common form of the disease, cutaneous anthrax, occurs when spores enter skin damaged by a cut or abrasion in persons involved in butchering or skinning an infected animal or working with the wool, hair, or hide in an industry that may be thousands of miles away.<sup>1,2,6,7,16-21</sup> There is circumstantial evidence that biting flies transmit anthrax not only to humans but also among animals.<sup>21,22</sup> Ingestion of raw or undercooked meat may cause a severe enteric disease that has been described mainly in tropical Africa and Asia. Inhalation of spores causes illness mainly in manufacturing settings, including the domestic weaving of contaminated wool.<sup>1,2,23-26</sup>

## DISEASE

The four clinical forms of human anthrax—cutaneous, oral-oropharyngeal, gastrointestinal, and inhalational—are

determined by the portal of entry of the etiologic bacterium. More than 90% of cases are cutaneous, and even if untreated 80% or more of these infections remain localized. A high proportion of patients with inhalational, oropharyngeal, gastrointestinal, and oral-oropharyngeal forms and approximately 20% of patients with the cutaneous form develop systemic bacteremia and succumb to the fatal effects of the anthrax toxins.

### Cutaneous Anthrax

Cutaneous anthrax occurs mainly on the exposed parts of the body, usually the hands, fingers, arms, face, or neck.<sup>1-3,17-22,27</sup> In greater than 90% of cases, there is a single lesion. After an incubation period of 1 to 7 days (usually 2 or 3 days), local pruritus is the initial symptom, followed within a day by a papule a few millimeters in diameter. Usually, on the second day one or more vesicles appear on the papule or in a ring around it. After enlargement or coalescence of the vesicles during the subsequent 1 to 3 days, the papule ruptures, forming a round 0.5- to 3-cm ulcer that dries to become a depressed, brown eschar that turns black, thick, and adherent to the underlying tissue during the next few days (Fig. 39-2). A characteristic feature of the eschar is that it is painless, and unless it is superinfected there is no pus. Many patients are afebrile, having no systemic signs or symptoms; others have headache, anorexia, nausea, malaise, and fever. Other significant clinical manifestations are regional lymphadenopathy and nonpitting edema around the eschar. The severity and extent of the edema are related to the overall severity of the infection and to the location of the lesion in an area with loose connective tissue. The edema itself can be fatal, particularly in the head and neck; tracheotomy may be required to

**FIGURE 39-2** Eschar of cutaneous anthrax that developed over a 5-day period from a small painless pruritic papule to a hemorrhagic bulla. The 20-year-old woman had been tending grazing goats. (Sethuraman G, Thappa DM, Karthikeyan K: Cutaneous anthrax. *Postgrad Med J* 76:472, 2000.)

avoid asphyxiation. Septicemic anthrax, whether occurring in association with cutaneous, gastrointestinal, or inhalational anthrax, is characterized by hematogenous lesions in the meninges and gastrointestinal tract in a substantial proportion of cases, as well as by the systemic effects of the toxin.<sup>28,29</sup> The local cutaneous lesion resolves slowly over 2 to 6 weeks, apparently without any effect of treatment and frequently with little trace after healing of the already established pathologic processes. In rare cases, complicating gangrene may require skin grafting and surgical reconstruction, particularly of the eyelid.

The skin lesion usually manifests edema involving, most prominently, the upper dermis (Fig. 39-3), with formation of a subepidermal bulla that is sloughed, leaving an ulcer. The fully formed eschar comprises coagulation necrosis of the skin with anthrax bacilli, vasculitis, edema, hemorrhage, and leukocytic exudate extending deep into the subcutaneous fat but not the skeletal muscle.<sup>29,30</sup> Experimental subcutaneous

inoculation of spores into chimpanzees demonstrated dose-dependent development of septicemic anthrax, with death occurring between days 3 and 7 after inoculation of  $5 \times 10^3$  to  $5 \times 10^4$  spores.<sup>31</sup> There was gelatinous edema of the surrounding skin and hemorrhagic necrosis of the draining lymph nodes.

### Oral-Oropharyngeal and Gastrointestinal Anthrax

Infection following the ingestion of meat of infected animals has been described frequently in Africa and Asia.<sup>5-8,32,33</sup> In oral-oropharyngeal anthrax, the pathologic lesions are visible, a history of eating raw or slightly cooked meat an average of 2 days beforehand is usually obtained, and epidemiologic association with cases of cutaneous anthrax is evident.<sup>32</sup> Presenting symptoms include swelling of the neck, fever, sore throat, and dysphagia.<sup>32-34</sup> Examination reveals soft tissue edema, regional lymphadenopathy, and mucosal lesions of the tonsils, posterior pharynx, base of the tongue, or hard palate. The lesion is initially congested and edematous and undergoes necrosis and ulceration by the end of the first week; early in the second week a pseudomembrane forms over the ulcer. A substantial portion of these patients recover following antibiotic treatment, but severely ill patients develop respiratory distress and may die of septicemic toxemia. The pathologic findings include mucosal ulceration, necrosis of underlying tissue, the presence of an overlying pseudomembrane, and hemorrhagic regional lymph nodes.

Gastrointestinal anthrax incidence is erratic, which presumably explains why infected animals are so regularly eaten. An outbreak of gastrointestinal anthrax occurred affecting 143 of 155 persons 15 to 72 hours after eating the meat of a dead zebra (91% gastrointestinal, 9% oropharyngeal).<sup>34</sup> Nine children died within 48 hours. Abdominal radiographs revealed gaseous distention, air-fluid levels, and ascites. Illness begins with low-grade fever, headache, and congestion of the face and conjunctivae followed 24 hours later by abdominal pain, nausea, vomiting, an ill-defined right lower

**FIGURE 39-3** Photomicrograph of skin in a case of cutaneous anthrax showing typical, marked dermal edema resulting in separation of collagen fibers together with vascular ectasia and a patchy mixed inflammatory cell infiltrate. (H&E stain;  $\times 160$ .) (Courtesy of Dr MJ Hale, The South African Institute for Medical Research.)

quadrant or periumbilical mass, abdominal distention, ascites, and hypovolemia.<sup>35</sup> Subsequent rapid increase in abdominal girth, paroxysmal abdominal pain, and occasionally gastrointestinal bleeding lead to shock. Exploratory laparotomy reveals abundant ascites and large, soft mesenteric lymph nodes, especially in the ileocecal region, and edema of the cecum, ascending colon, or a segment of small intestine. Infection presumably results from penetration of the mucosa by spores and subsequent germination to the vegetative form. In his experimental studies of anthrax in sheep, Pasteur had to mix the bacterial spores with feed containing thistle, probably to provide a mechanical lesion through which the spores entered the mucosa. The portal of entry is considered to be the cecum, ascending colon, or terminal ileum, where the pathologic findings are a solitary hemorrhagic, necrotic, edematous mucosal lesion and hemorrhagic mesenteric lymphadenitis, analogous to the lymphatic spread of fatal cutaneous or oral-oropharyngeal anthrax.<sup>36</sup> Cases in which the gastric mucosa contained the apparent primary lesions have also been described.<sup>29</sup> Patients with gastrointestinal anthrax present with fever, anorexia, nausea, and vomiting and later develop severe abdominal pain.<sup>5-8</sup> At least half the cases are fatal owing to septicemic toxemia and in some cases hemorrhagic, bacillus-laden ascites or gastrointestinal hemorrhage.

### Inhalational and Meningeal Anthrax

Inhalational anthrax occurs as an industrial disease associated with contaminated wool, hair, or other animal products, or as bioterrorism (see Chapter 15).<sup>23-26,37</sup> *B. anthracis* spores inhaled in particles smaller than 5  $\mu\text{m}$  in diameter are transported to the mediastinal lymph nodes, where they germinate, replicate, and secrete toxins that cause massive hemorrhage, edema, and necrosis in these nodes. The organisms and their toxins disseminate hematogenously with a nearly uniformly fatal outcome unless an effective antibiotic is used early in the illness.

Although anthrax meningoencephalitis is considered to result from hematogenous spread after entry in the skin, gastrointestinal tract, or lungs and from lymphogenous spread to the regional lymph nodes, patients have been described in whom no primary lesion was identified.<sup>38</sup> The case-fatality rate is around 34% even with treatment.

### PATHOGENESIS AND IMMUNITY

After germination, *B. anthracis* secretes three plasmid-encoded proteins: protective antigen, lethal factor, and edema factor, which act in combination as toxins.<sup>3</sup> Protective antigen, an 83-kD protein, binds by its C-terminal to a cell surface receptor, is cleaved by a host protease (furin) to yield a 63-kD polypeptide, and assembles into a heptameric  $\beta$ -barrel that is capable of binding lethal factor or edema factor. After endocytosis of the protective antigen-lethal factor/edema factor complex, acid-mediated conformational change, and insertion of the heptamer pore into the endocytic membrane, the lethal toxin and/or edema toxin are transported into the host cell cytoplasm.<sup>39-41</sup> Edema factor, an 89-kD protein, is a calmodulin-dependent adenylate cyclase that increases the intracellular cyclic adenosine monophosphate (AMP), resulting in the interstitial edema occurring around the eschar.<sup>42</sup>

Lethal factor is a zinc metalloprotease<sup>43</sup> with activity that digests mitogen-activated protein kinases 1, 2, 3, 4, 6, and 7.<sup>44</sup> Pathogenicity of *B. anthracis* requires the presence of the plasmid-encoded, antiphagocytic, poly-D-glutamic acid capsule.<sup>45</sup> A key pathologic lesion apparently explaining the lethal hemorrhagic meningitis and hematogenous hemorrhagic pneumonia of disseminated anthrax is vasculitis.<sup>46</sup> The induction of apoptosis in endothelial cells by lethal toxin may play a role in the vascular lesions.<sup>47</sup>

Immunity to anthrax requires immunization in which protective antigen is the most important stimulus of toxin-neutralizing antibodies although antigens of lethal factor, the spore, and cell wall also contribute to protection.

### DIAGNOSIS

The diagnosis of anthrax depends on recognition of the cutaneous or oropharyngeal lesion, typical signs and symptoms, history of exposure or potential exposure to an infected animal or its products, and laboratory confirmation by examination of a gram-stained smear of vesicle fluid, skin or oropharyngeal ulcer base, ascites, or pleural or cerebrospinal fluid; culture; immunohistochemical identification of *B. anthracis*; or serologic studies. The preceding pruritus, ring of vesicles, black eschar, absence of pain and pus, and presence of edema surrounding the cutaneous lesion are diagnostically suggestive. The differential diagnosis of cutaneous anthrax includes staphylococcal boil, syphilitic chancre, ulceroglandular tularemia or plague, rickettsial eschar, brown recluse spider bite, burn wound, ecthyma gangrenosa, milker's nodule, and orf. The differential diagnosis of oral-oropharyngeal anthrax includes diphtheria and peritonsillar abscess. Gastrointestinal anthrax and anthrax meningitis could present with similar signs and symptoms to gastroenteritis or meningitis caused by many agents. In its early stages, inhalational anthrax resembles influenza or other viral upper respiratory infections. An important diagnostic clue is radiographic widening of the mediastinum owing to edema, hemorrhage, and necrosis. Diagnosis, especially in samples of animal blood, is confirmed by the M'Fadyean stain, which demonstrates a pink capsule surrounding dark-blue, often square-ended bacilli.<sup>3,48</sup> Nonhemolytic tenacious colonies of nonmotile, penicillin-sensitive, gram-positive bacilli are recovered from vesicle fluid, eschar, tonsillar ulcer, blood, ascites, or cerebrospinal fluid on 5% sheep blood agar. Specific identification is achieved by lysis with a specific  $\gamma$ -bacteriophage or by staining with monoclonal antibodies to the capsule and cell wall antigens.

A specific inhibition enzyme immunoassay for antibodies directed against purified protective antigen has been used to establish a diagnosis in cases of cutaneous anthrax.<sup>9,30</sup>

### TREATMENT

Cutaneous anthrax had a case-fatality rate of 16% in the preantibiotic era during the period 1933-1938. One physician cared for 116 cases of cutaneous anthrax between 1933 and 1955, using antianthrax serum in the first 21 cases, sulfonamides in the 56 patients between 1939 and 1947, and penicillin, a tetracycline (27 patients), chloramphenicol (7 patients), or erythromycin (2 patients), thereafter.<sup>17</sup> After 1933, no deaths occurred as all the treatment regimens proved

to be of increasing effectiveness. Early in its use penicillin was administered in doses as low as 50,000 to 100,000 units daily.<sup>49</sup> After doses of 100,000 to 200,000 units/d for 3 days, no bacteria could be recovered from 90% of the cutaneous lesions. Two million units of intravenous penicillin sterilizes blister fluid in 5 hours.

For cutaneous anthrax, oral potassium penicillin V (30 mg/kg body weight per day in four divided doses every 6 hours for 5 to 7 days) is recommended. In more severely ill patients, intramuscular procaine penicillin G aqueous (34,000 units/kg body weight per day divided into two equal doses given every 12 hours) is often given. For penicillin-allergic patients, tetracycline, ciprofloxacin, erythromycin, or chloramphenicol can be used.

For systemic anthrax (septicemic, inhalational, gastrointestinal, or oropharyngeal) high-dose intravenous penicillin G is the treatment of choice. Ciprofloxacin (400 mg intravenously every 12 hours or 100 mg doxycycline intravenously every 12 hours) has been used to treat systemic anthrax sepsis.<sup>34</sup> Streptomycin, erythromycin, and tetracycline have also been used. Intensive supportive care is often necessary.

Surgical excision of the cutaneous lesion or incision of a subcutaneous or tonsillar lesion does not improve the outcome nor does it yield any drainage of pus because there is none. Indeed, exacerbation of the local injury may ensue.

## PREVENTION AND CONTROL

Prevention of human anthrax depends on prevention of animal anthrax as has largely been achieved in Europe and the United States. In Zimbabwe during the period October 1979–1980 when civil and military conditions stopped effective animal vaccination programs, there were more than 6000 cases of human anthrax compared with fewer than 500 cases during the entire period 1923–1977.<sup>20–22</sup> In South Africa, animal vaccinations provided free, beginning in 1923, reduced the annual outbreaks of anthrax in cattle from approximately 1000 to fewer than three.<sup>48</sup> The effective veterinary vaccine consists of viable *B. anthracis* spores that contain the plasmid for production of protective antigen, lethal factor, and edema factor but lack the plasmid with genes for synthesis of the capsule.<sup>48</sup> Control measures include quarantine of animals on farms where cases have been confirmed, vaccination of all livestock on the farm and adjacent areas, treatment of animals with antibiotics (antibiotics must not be given 10 days before or after vaccination to avoid killing the live attenuated bacterial vaccine), isolation and destruction of infected animals, incineration or burial of infected carcasses with slaked lime, and disinfection of the premises with 5% formaldehyde.

Humans are protected by public awareness programs regarding the dangers of contact with the infected animals or their meat and products. Vaccines have been developed for human use; a live spore vaccine similar to the Sterne veterinary vaccine has been used effectively in the former USSR.<sup>50</sup> Dynaport produces a nonliving vaccine that contains protective antigen and requires a primary series of inoculations as well as booster vaccinations.

Prophylactic antibiotics are ineffective in preventing inhalational anthrax unless given for 6 days, preferably in conjunction with vaccination on days 1 and 15.<sup>51</sup> Oral penicillin prophylaxis has been used following ingestion of known

contaminated meat and after cutaneous injection of virulent organisms.

## INTRODUCTION

The genus *Bartonella* includes *B. bacilliformis*, the etiologic agent of a sandfly-transmitted febrile hemolytic anemia (Oroya fever) and chronic cutaneous angiomatosis (verruca peruana) endemic to Andean tropical Peru, Ecuador, and Colombia; *B. (formerly Rochalimaea) quintana*, the causative agent of trench fever during World Wars I and II and currently among the louse-infested poor; *B. henselae*, the major cause of cat-scratch disease (Table 40-1); *B. (formerly Rochalimaea) vinsonii*, until recently not considered to be a pathogen; *B. elizabethae*, an etiologic agent of infective endocarditis (as are *B. henselae*, *B. quintana*, and *B. vinsonii*); and several newly discovered species and others formerly assigned to the genus *Grahamella*, that cause persistent asymptomatic infections of wild rodents in both tropical and temperate regions.<sup>1-5</sup> In immunocompromised persons, particularly those infected with human immunodeficiency virus (HIV), *B. henselae* and *B. quintana* cause opportunistic infections, frequently manifested as cutaneous bacillary angiomatosis resembling verruca peruana.<sup>6</sup> Bartonellae are members of the  $\alpha$ -Proteobacteria group, which also contains the genera *Rickettsia*, *Ehrlichia*, and *Brucella*, and *Agrobacterium tumefaciens*, a plant pathogen, all of which have evolved from a common ancestor.

Pre-Columbian evidence of South American bartonellosis includes artistic representations in pottery and stone as well as lesions in a mummy.<sup>7-9</sup> The Spanish conquistadors in Ecuador and soldiers dispatched to quell the rebellion of Diego de Almagro developed illnesses characterized by systemic symptoms and numerous cutaneous lesions that persisted for months, which were documented by chronicles contemporary with the events. The verruca peruana form of the illness was described in colonial times and was illustrated by a medical photograph in the 1856 medical thesis of Dr. Tomás Salazar. The acute hemolytic form of *B. bacilliformis* infection occurred catastrophically during the construction of Peru's Central Railway, which includes 61 bridges from Lima to Oroya, from which the designation Oroya fever is derived.<sup>7,8,10</sup> At least 7000 workers died between 1869 and 1873 as the railroad construction passed from 1000 to 3000 m above sea level, roughly along the Rimac River valley, where the sandfly vector abounds. The city of Oroya, at 3800 m elevation, has always been free of the disease. The connection between

**Table 40-1** Etiology and Transmission of Human Bartonelloses

Agent	Disease	Vector
<i>B. bacilliformis</i>	Oroya fever (acute) Verruca peruana (chronic)	<i>Lutzomyia verrucarum</i> (sandfly)
<i>B. quintana</i>	Trench fever  Bacillary angiomatosis Endocarditis	<i>Pediculus humanus corporis</i> (louse)
<i>B. henselae</i>	Cat-scratch disease  Bacillary angiomatosis Endocarditis	Cats and <i>Ctenocephalides felis</i> (flea)
<i>B. elizabethae</i> and <i>B. vinsonii</i>	Endocarditis	Presumably fleas and ticks

Oroya fever and verruca peruana was vividly and dramatically demonstrated by a Peruvian medical student, Daniel Carrión, who, seeking to prove that the cutaneous disease was infectious, had himself inoculated experimentally with material from a patient's skin lesion.<sup>7-11</sup> Only as death from severe febrile disease and anemia approached did he realize that the verruca had contained the etiologic agent of Oroya fever. Both manifestations of the infection are now known as Carrión's disease. The Peruvian physician Alberto Barton is credited with the first visualization of the causative bacteria within circulating erythrocytes of patients with Oroya fever in 1905. Battistini, a Peruvian physician working in collaboration with Noguchi's laboratory at the Rockefeller Institute, was apparently the first to regularly cultivate *B. bacilliformis*, and in 1926 Noguchi purportedly cultivated the organism from verruca lesions obtained from Peru.

During the severe trench fever epidemic involving a million persons during World War I, *B. quintana* was considered to be related to rickettsiae because it was found in lice and could not be cultivated.<sup>12</sup> In 1961 Vinson and Fuller<sup>13</sup> reported the isolation of the etiologic agent after prolonged cultivation on blood agar; subsequent infection of human volunteers with this isolate fulfilled Koch's postulates.<sup>14</sup>

Visualization of bacteria in silver-stained lesions of cat-scratch disease in 1983 and the discovery in 1990 that the sequence of a polymerase chain reaction (PCR) product of the 16S ribosomal DNA (rDNA) from bacillary angiomatosis lesions was the same as that from a novel species, *B. henselae*, isolated from the blood of immunocompromised patients, were important milestones in the elucidation of the medical importance of this organism.<sup>15-19</sup> Subsequently, cat-scratch disease patients were shown to develop antibodies to *B. henselae* and to be infected with this bacterium.<sup>20</sup>

## AGENTS

*B. bacilliformis* is an aerobic, facultative intracellular 1- to 3- $\mu$ m pleomorphic bacillus with a poorly staining gram-negative

cell wall and 2 to 16 unipolar flagella conferring a high degree of motility.<sup>21</sup> *B. henselae* exhibits a characteristic twitching movement and has been demonstrated to have type IV pili.<sup>22</sup> *B. henselae* and *B. quintana* are metabolically rather inert in that they test negative for glucose oxidation, indole production, nitrate reduction, and catalase, oxidase, and urease activity.

Bartonellae require hemin, with *B. quintana* having the highest hemin requirement for growth among bacteria.<sup>23</sup> *B. quintana* has five heme receptors that are all expressed and are predicted to be  $\beta$ -barrel outer membrane proteins with eight transmembrane domains and four extracellular loops. The *ialA* invasion gene of *B. bacilliformis* is a dinucleoside polyphosphate hydrolase more similar to eukaryotic plant diadenosine tetraphosphate hydrolases than to the bacterial enzymes.<sup>24</sup> It is considered likely that it removes the toxic substrate that accumulates during invasion and oxidative stress generated by host defenses with useful ATP as a byproduct of its catabolism.

Growth of bartonellae is slow, requires 5% CO<sub>2</sub>, hemin, and an optimal temperature of 35°C for *B. quintana* and *B. henselae* and 28°C for *B. bacilliformis*.

## EPIDEMIOLOGY

The reservoir host of *B. bacilliformis* is the human, who may remain persistently bacteremic for months after recovery from the clinical illness.<sup>25–28</sup> A wildlife reservoir was postulated, since isolated cases have occurred in persons exposed to vectors for a single night in deserted areas.<sup>29</sup> However, no confirmed isolations of *B. bacilliformis* have been obtained from fauna in the endemic areas. The classically accepted vector in Peru is the female hematophagous sandfly, *Lutzomyia*

*verrucarum*, which is found in narrow river valleys between 500 and 3200 m above sea level. More recently, cases have occurred in high rainforest regions.<sup>30</sup> South American bartonellosis also occurs in Colombia and Ecuador, where *L. verrucarum* is absent.<sup>31</sup> The most likely vector in Colombia is the highly anthropophilic *L. columbiana*, but at present the disease is apparently seldom documented in Colombia.<sup>12,27</sup> The probable vectors in Ecuador, where cases occur in low-lying coastal areas as well as the Andes, are unknown. Although sandflies are incompletely studied in South America, more than 500 different species have been described with two thirds of them in the Americas, more than 60 in Ecuador, and approximately 120 in Peru.<sup>32,33</sup> Serologic studies suggest that in endemic areas more than 60% of the population has been infected.<sup>34</sup> In such populations 0.5% to 10% are bacteremic at any given time.<sup>25,27,35</sup> A prospective population-based study in an endemic site identified a high incidence (12.7 infections/100 person-years) that was greatest in children less than 5 years of age and declined with age.<sup>35</sup> The affected pediatric population commonly belongs to a low income population. Higher incidence was associated with the increased humidity, temperature, and sandfly population during El Niño-influenced weather. As expected with a human reservoir and transmission by indoor sandfly bites in the evening and night, 70% of cases clustered in 18% of households. Mothers in endemic areas expect the verruga to occur in their children and are concerned if, after a certain febrile illness that they consider to be bartonellosis, the children do not develop the skin lesions, fearing more severe complications and death. Epidemics occur when immunologically naive persons are exposed to the infection because of population migration or introduction of infected sandflies.<sup>7,28</sup>

*Bartonella bacilliformis*

■ Global distribution

The human louse, *Pediculus humanus corporis*, was recognized as the human-to-human vector of epidemic trench fever in the European theaters of World Wars I and II. *B. quintana* infections have also occurred in the past in North Africa, Ethiopia, Japan, China, Mexico, and Bolivia and more recently in the United States and France among immunocompromised patients, particularly those with HIV infection, as well as among homeless persons who abuse alcohol.<sup>12,13,36–40</sup> After immunocompetent persons recover from untreated *B. quintana* infection, asymptomatic bacteremia may continue for months. It is likely that *B. quintana* is a prevalent but as yet poorly recognized agent of human infections in the tropics.<sup>41</sup>

The reservoir of *B. henselae* is the domestic cat throughout the world, particularly in warm, humid climates where *Ctenocephalides felis* cat fleas thrive.<sup>42,43</sup> A substantial proportion of domestic cats are infected, and bacteremia is prolonged, lasting months to more than a year.<sup>42,44</sup> Cat fleas transmit *B. henselae* between cats and possibly by contaminating cat scratch or bite wounds with flea feces.<sup>45,46</sup> The bacteria remain infectious in flea feces for prolonged periods. There are two genotypes of *B. henselae* that have variable prevalences in different geographic regions with imperfect concordance between the distributions of human and cat genotypes.<sup>47,48</sup> Cat-scratch disease and other manifestations of *B. henselae* infection occur throughout the tropics, although their particular manifestations in some of these areas are yet to be described.

*Bartonella* endocarditis, most frequently caused by *B. quintana* or *B. henselae*, is not related to the immune status of the host but rather to the risk factors for infection.<sup>49</sup> Case reports of endocarditis caused by *B. elizabethae* or *B. vinsonii* subsp. *berkhoffii*, of myocarditis caused by *B. washoensis*, of neuroretinitis caused by *B. grahamii*, and of bacteremia caused by *B. vinsonii* subsp. *arupensis* are difficult to link with the natural reservoir-vector cycles.<sup>50,51</sup> Conversely high seroprevalence of antibodies to rat-associated *B. elizabethae* among urban intravenous drug abusers has not been correlated with clinical manifestations.<sup>52</sup>

## DISEASES

The incubation period of South American bartonellosis is considered to be 21 days (from Carrión's experimental case) with a range of 1 to 30 weeks and a mean of 2 months. The two clinical forms of the disease—Oroya fever and verruga peruana—may occur sequentially, sometimes with an intervening clinically silent period, or either form may occur alone.<sup>7,10,26–28,53,54</sup> The usual gradual onset of systemic symptoms of malaise, somnolence, anorexia, myalgia, headache, pain in the back and extremities, chills, and fever accompany erythrocyte parasitization levels as high as 100%. The mononuclear phagocytic system removes and destroys a major portion of the infected red blood cells after 2 to 4 weeks, resulting in severe anemia with erythrocyte counts in some cases below 10% $\mu$ L, accompanied by hepatosplenomegaly, generalized lymphadenopathy, jaundice, dyspnea, and mental status changes.<sup>27,55,56</sup> The facultative intracellular bartonellae invade endothelial cells, particularly in skin and lymph nodes. Patients with severe infection develop pericardial effusion, myocarditis, coma, convulsions, delirium, acute respiratory distress, anasarca, acute renal failure, and multiple organ failure.<sup>57,58</sup> Infection during pregnancy may result in transplacental infection, abortion, fetal death, and maternal death. The duration

of Oroya fever is between 1 and 6 weeks with variation from mild to fatal in approximately 40% of patients during the pre-antibiotic era, 8% currently in hospital settings, 88% in a recent outbreak in a remote rural area, and 0.7% in a contemporary population-based study.<sup>28,56</sup> Death frequently occurs owing to infection-induced immunodeficiency and consequent opportunistic infections that intervene in 30% of cases caused by bacteria (e.g., salmonellae, staphylococci, or *Mycobacterium tuberculosis*), protozoa (e.g., *Toxoplasma* or amoebae), fungi (e.g., *Histoplasma* or *Pneumocystis*), and viruses (e.g., herpesvirus or hepatitis B virus).<sup>11</sup> Salmonellosis was formerly the most frequent fatal complication in hospitalized patients.<sup>59</sup> Inversion of the T lymphocyte helper and suppressor subset ratio and development of skin test anergy reflect transient immunosuppression underlying the appearance of opportunistic infections.<sup>60</sup> Persistent bacteremia by *Bartonella bacilliformis* has been described in a splenectomized patient.<sup>61</sup>

Two to 20 weeks after recovery from Oroya fever or without any preceding illness, arthralgia, fever, and a series of crops of verrucae appear as painless erythematous 0.2- to 4-cm papules, sessile or subdermal nodules, or large angioma-like cutaneous lesions (Fig. 40-1). The lesions are prone to bleed and occur particularly on the head and extremities; sometimes they also occur on the nasal, conjunctival, and oral mucosa, but they

**FIGURE 40-1** Verruga peruana skin lesions on the foot and leg of a patient from Peru infected with *B. bacilliformis*.

have never been described in internal organs. Histologically, these lesions consist of proliferations of vascular endothelial cells and dermal dendrocytes with interspersed macrophages, lymphocytes, and plasma cells.<sup>62–64</sup> In verrucae, bartonellae are observed extracellularly.<sup>62,63</sup> Individual verrucae dry up and slough in a few weeks, leaving no scars. Crops of verrucae can occur for months or exceptionally for years.<sup>65,66</sup> In an endemic area, 11% of infections were acute hematic Oroya fever; 37% of the infected population had verruga peruana preceded by symptoms of Oroya fever, 31.5% developed verruga peruana without preceding acute hematic illness, and 20.5% were asymptomatic. Overall only 7% of this medically underserved population were hospitalized, and none died.<sup>35</sup> In an outbreak in a nonendemic area where the disease had not previously occurred, 77.5% of the population developed antibodies against *B. bacilliformis*, 13.8% had symptoms (fever, headache, and bone and joint pain) of Oroya fever, and verruga peruana occurred in 17.6% with only 4.8% of the population manifesting the biphasic course.<sup>67</sup>

Trench fever or acute *B. quintana* infection has a variable incubation period that averages 8 days.<sup>12,14,36</sup> The clinical course varies from mild and afebrile to moderately severe with a long clinical course and numerous relapses. Some patients suffer a single febrile episode of 4 to 5 days often accompanied by malaise, headache, pain that is particularly severe in the shins, and an evanescent rash that is visible mainly in lightly pigmented skin. Other patients have continuous fever for up to 6 weeks or a course with three to eight periodic febrile episodes of about 5 days' duration from which the name *B. quintana* is derived. Contemporary *B. quintana* infection of homeless alcoholic persons is typically manifested only as fever unless associated with *Bartonella* endocarditis.<sup>37–39</sup> Yet among homeless French persons, 14% are bacteremic, 80% of whom are afebrile. Prolonged *B. quintana* bacteremia can persist for 300 to 443 days after onset. In Europe, chronic lymphadenopathy has been associated with granulomatous *B. quintana* infection of the lymph nodes.<sup>68</sup> Immunocompromised patients, especially those with the acquired immunodeficiency syndrome (AIDS), develop disseminated angioma-like lesions of the skin and viscera, bacillary angiomatosis, and bacillary peliosis that are indistinguishable from those produced by *B. henselae*.<sup>6,16</sup>

The clinical manifestations of *B. henselae* infection include cat-scratch disease, unilateral follicular conjunctivitis, neuroretinitis, retinochoroiditis, encephalitis, meningitis, encephalopathy, persistent or relapsing febrile bacteremia, hepatosplenic lesions, infective endocarditis, osteomyelitis, atypical pneumonia, erythema nodosum, bacillary angiomatosis, bacillary peliosis, and inflammatory or vasoproliferative lesions in virtually any organ.<sup>6,16–19,42,47,69–79</sup> Cat-scratch disease is manifest as a papule at the site of inoculation of organisms by cat scratch or bite and regional lymphadenopathy with or without fever in 25% to 60% of patients 3 to 12 days after injury and 1 to 2 weeks before onset of constitutional symptoms. *B. henselae* stimulates an inflammatory reaction in immunocompetent hosts manifest most often as regional (epitrochlear, axillary, and/or cervical) lymphadenopathy that resolves in a median of 7 weeks and undergoes suppuration in 15%. Peruvian studies have detected antibodies to *B. henselae* and *B. clarridgeiae*.<sup>80,81</sup> The formation of mature granulomas leads to the elimination of the organisms. In immunocompromised patients, *B. henselae* and *B. quintana* infections stimulate the proliferation and

migration of endothelial cells, resulting in cutaneous bacillary angiomatosis and in some patients similar vascular proliferations in the spleen and liver (bacillary peliosis), lymph node, lung, bone, gastrointestinal tract, brain, mouth, nose, and anus.<sup>82</sup> The lesions resemble verruga peruana with lobular proliferations of endothelial cells.<sup>83</sup> They also contain neutrophils, leukocytoclastic debris, and extracellular amorphous granular material that is revealed by Warthin-Starry silver staining to be microcolonies of bartonellae. Although *B. henselae* and *B. quintana* are facultative intracellular bacteria, intracellular bartonellae (Rocha-Lima bodies) are not characteristic of *B. henselae* and *B. quintana* bacillary angiomatosis.<sup>22</sup> In some patients, the disseminated lesions are neither angioma-like nor granulomatous but rather a mixture of nonspecific inflammation and fibrosis.

*Bartonella* endocarditis affects mainly middle aged patients who present with fever (83%), often develop emboli (43%) from the large vegetations that involve the aortic valve more often than the mitral valve, and occasionally suffer renal failure owing to mesangioproliferative glomerulonephritis.<sup>49</sup> *Bartonella henselae* most often affects previously damaged valves, and *B. quintana*, previously normal valves. Chronic myocarditis has been reported in association with evidence for *Bartonella* infections.<sup>84,85</sup>

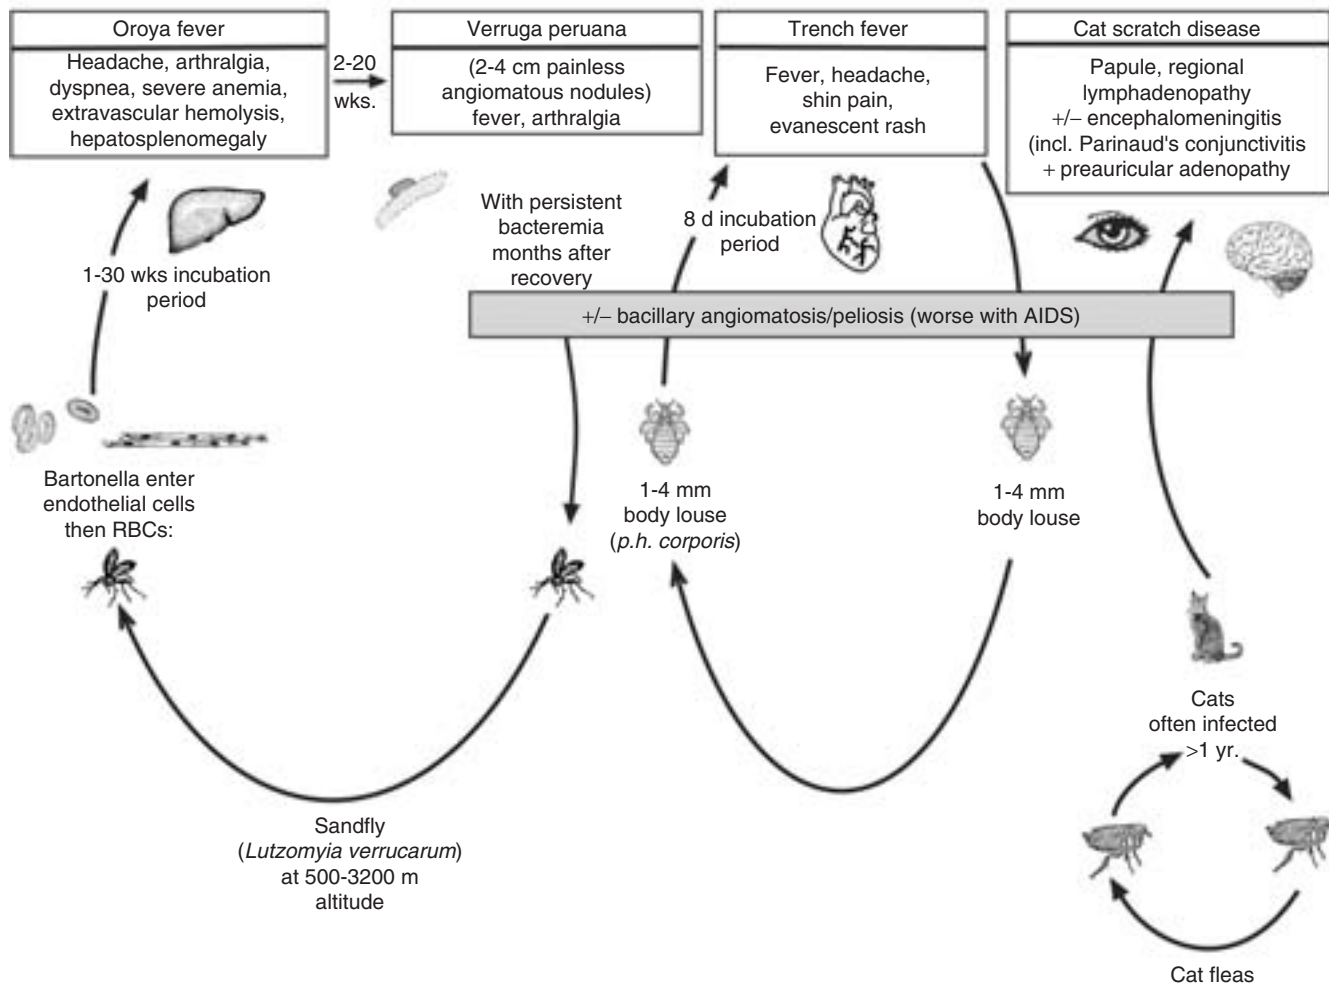

## PATHOGENESIS AND IMMUNITY

In Oroya fever, the facultatively intracellular *B. bacilliformis* is introduced into the vasculature by the bite of a sandfly and is taken up by endothelial cells of capillaries, sinusoidal lining cells, and red blood cells.<sup>86–88</sup> Bartonellae induce invaginations in the erythrocyte cell membrane by a small uncharacterized molecule—deformin—and enter the red blood cell using proteins encoded in a two-gene locus together with motive force from flagella.<sup>21,89–93</sup> Entry of *B. bacilliformis* into endothelial cells is dependent on Rho-GTPase, which is activated by the bacteria.<sup>94</sup> *Bartonella quintana* circulate inside 0.001% to 0.005% of human erythrocytes, sequestered from immune attack.<sup>95</sup> Although in vitro cultivation of *B. quintana* in human red blood cells shortens the cells' lifespan, anemia does not occur in marked contrast with extravascular hemolysis in Oroya fever.<sup>95,96</sup> Experimental infection of rats with *B. tribocorum* having deletions in the type IV secretion components *virB4* or *virD4* demonstrated the requirement of these genes for establishment of intraerythrocytic infections.<sup>97</sup>

The pathogenesis of enhanced angiogenesis in *Bartonella*-associated verruga peruana, bacillary angiomatosis, and peliosis may involve endothelial mitogenic factors (e.g., GroEL) secreted by the bacteria, paracrine and autocrine angiogenic effects of vascular endothelial growth factor from macrophages and overlying epidermis, interleukin (IL)-1 $\beta$  from macrophages and IL-8 and angiopoietin 2 from endothelial cells, inhibition of endothelial apoptosis by an unidentified bacterial component, and possibly decreased levels of antiangiogenic IL-12 and IFN- $\gamma$  in immunocompromised persons.<sup>98–100</sup>

Host defenses against bartonellae involve strong cell-mediated immunity associated with delayed-type sensitivity and Th1-type cytokines (IFN- $\gamma$  and IL-12). Homeless persons with chronic *B. quintana* bacteremia lack specific antibodies and have lower production of TNF- $\alpha$ , IL-1 $\beta$ , and IL-6 by peripheral blood mononuclear cells and greater production of immunosuppressive IL-10 after *B. quintana* stimulation, which may

**Bartonella infections:**  
**Oroya fever (*B. bacilliformis*)**  
**Trench fever (*B. quintana*<sup>1</sup>)**  
**Cat scratch disease (*B. henselae*)**

underlie the failure of the immune system to clear the infection.<sup>101</sup> Antibodies clear bartonellae when they are released from infected erythrocytes.<sup>102</sup>

## DIAGNOSIS

Oroya fever, with an early clinical differential diagnosis including typhoid fever, malaria, brucellosis, hepatitis, tuberculosis, leptospirosis, sepsis, sylvatic yellow fever, typhus, paracoccidioidomycosis, histoplasmosis, hematologic malignancy, and hemolytic or aplastic anemia, can be diagnosed by detection of *B. bacilliformis* within erythrocytes in stained blood smears (Fig. 40-2). Caution is recommended, however, because of the frequency of artifacts.<sup>27,53</sup> Epidemiologic data are essential. The bacteria can be cultivated from blood in 71% to 83% of cases by incubating for up to 6 weeks at 28°C on Columbia agar supplemented with 5% defibrinated blood or other blood- or hemin-supplemented media, with detection of colonies after a average of 18 days. Diagnosis can also be achieved by PCR even on blood spotted onto a card and

can be differentiated from other bartonellae.<sup>35,103-105</sup> Serologic diagnosis of *B. bacilliformis* infection can be established by enzyme immunoassay, IgM or IgG indirect immunofluorescence, indirect hemagglutination and immunoblot detection of a 17- or 18-kDa antigen.<sup>34,67</sup> The diagnosis of verruga peruana, for which the clinical differential diagnosis includes hemangiomas, pyogenic granuloma, bacillary angiomatosis, Kaposi's sarcoma, chickenpox, molluscum contagiosum, and malignant melanoma can be confirmed by histopathology.<sup>62,66,106</sup> Culture of *B. bacilliformis* from the skin lesions is difficult because of frequent contamination and its slow growth rate.

The diagnosis of cat-scratch disease, which formerly relied upon clinical criteria, delayed-type hypersensitivity to a crude skin test material derived from human infected tissues containing antigens of *B. henselae*, and histopathology, now can be established by immunofluorescence antibody (IFA) test, enzyme immunoassay serology, culture, or PCR of lymph node aspirate or biopsy.<sup>20,70</sup> IFA serology provides best results with low passage bacterial antigen cocultivated with cells.

**FIGURE 40-2** Peripheral blood smear of a Peruvian patient with Oroya fever. A high portion of erythrocytes contain *Bartonella bacilliformis*.

Agar-grown antigens yield lower titers, and end point titers vary with different commercial products. Thus, a fourfold rise in titer or seroconversion is more convincing than a single high titer. Enzyme immunoassay serology for cat-scratch disease detects IgM antibodies in 53% of sera during the first 3 months, reverting to negative thereafter. IgG antibodies are detected in 92% although initially negative in 28% followed by seroconversion. IgG antibodies are still detectable in only 25% of patients after 1 year.<sup>80</sup> There is considerable serologic cross-reactivity between *B. quintana* and *B. henselae*. Bacteremia with *B. quintana* or *B. henselae* can be diagnosed by saponin or EDTA freeze-thaw lysis of erythrocytes to release intracellular bartonellae, followed by centrifugation and incubation at 35°C in a humid 5% CO<sub>2</sub> atmosphere on chocolate or Columbia blood agar for more than a month, for colonial growth to be visible.<sup>48,107</sup> Organisms are identified by twitching motility in wet mounts, immunofluorescent staining with specific antibodies, and molecular methods. In a recent large series of cases of cat-scratch disease, *B. henselae* DNA was detected by PCR in 31% of lymph node biopsies and 55% of lymph node aspirates, and *B. henselae* was isolated from 27% of lymph node biopsies and 11% of lymph node aspirates after a median of 21 days.<sup>48</sup> The most cost-effective diagnosis of cat-scratch disease relies on the combination of clinical manifestations and serology. The etiologic diagnosis of bacillary angiomatosis and *Bartonella* endocarditis can be established on resected tissues by a combination of histopathology and immunohistology, PCR, or culture.<sup>37,83,108</sup> *Bartonella* antibodies are usually absent in immunocompromised patients with bacillary angiomatosis. *Bartonella* endocarditis is diagnosed more effectively by real-time PCR than by culture, and an IFA titer of at least 800 is strongly supportive of the diagnosis.<sup>48,109</sup> The species of *Bartonella* endocarditis can be determined by cross-absorption immunoblotting.<sup>110</sup>

## TREATMENT

Oroya fever was treated traditionally with chloramphenicol (50 mg/kg/d up to 3 g/d) and after defervescence with half

the dose for 10 days because of chloramphenicol's activity against salmonellosis, a classically described life-threatening secondary infection.<sup>56,111</sup> In recent years, therapeutic failure with chloramphenicol due to overwhelming infections (e.g., *Pseudomonas* sp, *Enterobacter* sp, *Acinetobacter* sp) has changed the drug of choice to ciprofloxacin in children and adults. The dosage of ciprofloxacin for the acute phase is 500 mg bid orally for 10 days. The dosage for children younger than 15 years is 250 mg bid orally for 10 days.<sup>112</sup> Mutations of *gyrA* in organisms grown in the presence of ciprofloxacin suggest the potential development of resistance.<sup>113</sup> Transfusions of packed red blood cells may be needed to treat the severe anemia in approximately 10% of patients. It must be remembered that throughout the disease the bone marrow is hyperactive, liberating immature erythrocyte precursors. Once the infection is under control, recovery from anemia is surprisingly prompt. For severe cerebral complications (coma, convulsions due to cerebral hypoxia, and edema), short courses of dexamethasone have been employed.<sup>111</sup> The verrucae can be treated with oral rifampin (10 mg/kg/d for 14 to 21 days), which is more effective and convenient than the formerly used streptomycin. Alternative drugs are oral erythromycin, ciprofloxacin, and azithromycin.<sup>66,112,114,115</sup>

The signs of uncomplicated cat-scratch disease are mainly the manifestations of an effective immune response, and antibiotic treatment has little or no effect on the course of disease although azithromycin may hasten the resolution of lymphadenopathy.<sup>116</sup> In vitro susceptibility tests for *B. quintana* and *B. henselae* correlate poorly with clinical experience. Many antimicrobial agents are bacteriostatic, but aminoglycosides such as gentamicin are bactericidal against *B. henselae*.<sup>114,117</sup> Ocular bartonellosis is treated with doxycycline (100 mg every 12 hours) because of superior ocular penetration with a 2- to 4-week course in immunocompetent patients and 4 months or longer in immunocompromised patients.<sup>78</sup> In practice, bacillary angiomatosis is treated with oral doxycycline (100 mg twice a day) or oral erythromycin (0.5 to 1.0 g four times a day) for 2 to 3 months and longer if resolution is incomplete or relapse occurs. Oral tetracycline, minocycline, chloramphenicol, clarithromycin, and azithromycin have also been used successfully. In a series of 101 patients with *Bartonella* endocarditis, among whom 12 died and two suffered relapses, full recovery was more likely if the patient was treated with an aminoglycoside, and survival was more likely if the patient was treated for a minimum of 14 days with an aminoglycoside.<sup>49</sup> Endocarditis and, in many cases, bacteremia and visceral bacillary angiomatosis or peliosis are treated intravenously. *Bartonella* endocarditis requires cardiac valve replacement in 76% of cases usually for hemodynamic reasons. The intraerythrocytic niche of *B. quintana* presents a therapeutic challenge. Testing of antimicrobial agents against intraerythrocytic *B. quintana* revealed that doxycycline, fluoroquinolones, and  $\beta$ -lactams are not bactericidal, gentamicin and rifampin are bactericidal at 4  $\mu$ g/mL, but the peak intraerythrocytic concentration of gentamicin (0.26  $\mu$ g/mL) occurs after 24 hours and is not bactericidal.<sup>96</sup> Most likely gentamicin kills *B. quintana* only after its release from red blood cells. Chronic *B. quintana* bacteremia in homeless persons was effectively cleared by treatment with gentamicin (3 mg/kg in one IV dose daily) for 14 days followed by oral doxycycline (200 mg/d) for 28 days.<sup>118</sup>

## PREVENTION AND CONTROL

Control efforts for *B. bacilliformis* infections are directed mainly against adult sandflies. Peridomestic exposure to *Lutzomyia* is reduced by spraying houses, nearby animal shelters, and other structures with residual insecticides and by the use of fine-mesh screens. Area control of sylvan sandflies is not currently achievable, and resistance to insecticides is at least a potential concern. Individual protection using insect repellants and fine-mesh bednets is feasible and in endemic areas should focus on infants and children. An effective measure for workers in endemic areas is to leave the dangerous areas before dusk and set up camp elsewhere; in the Andes, a relatively short distance may mean a difference of several hundred meters in elevation.

Reduction in *B. henselae* transmission can be achieved via elimination of cat fleas and avoidance of traumatic injury by cats. Prophylaxis for *Mycobacterium avium* complex infections or other reasons with macrolides seems to protect also against *Bartonella* infections in HIV-infected persons.<sup>119</sup>

Control of trench fever depends on destroying human body lice with insecticides and improved socioeconomic conditions that make it possible to kill lice as clothes are washed routinely in hot, soapy water. Intensive treatment of human infections would reduce the reservoir of *B. quintana*.

Reduction of infection in the known reservoirs of bartonellosis, for example, humans (*B. bacilliformis* and *B. quintana*) and cats (*B. henselae*), could be theoretically be accomplished by vaccination. It is also conceivable that an agent for which there is no nonhuman reservoir, such as *B. bacilliformis* and *B. quintana*, might eventually be eradicated.

# Brucellosis

EDUARDO GOTUZZO

## INTRODUCTION

In 1885, Sir David Bruce described “a disease of long duration with fever, profuse perspiration, splenomegaly, frequent relapses, rheumatoid or neuralgic pain, swelling of the joints and orchitis” seen in his patients in Malta, and he isolated the pathogen from the spleen of his autopsy studies.<sup>1</sup> Brucellosis still poses important problems in animals and humans in some regions of the world.<sup>2–4</sup>

## AGENT

*Brucella* is a slow-growing, aerobic, catalase-positive, non-motile gram-negative coccobacillus in the  $\alpha$ -proteobacteria ( $\alpha$ -2 group) with *Bartonella* (*Rochalimaea*) *henselae* and *Agrobacterium tumefaciens*.<sup>5,6</sup> The *Brucella* species that infect humans are all now considered to be biovars of *B. melitensis* (the cause of Malta fever with the goat reservoir), but traditionally have also included *B. abortus* (the cause of Bang's diseases and abortions in cattle), *B. suis* (from aborting swine), *B. canis* (from aborting beagle dogs), and two other organisms that are considered nonpathogenic to humans that have been isolated from sheep and wood rats, respectively (*B. ovis* and *B. neotomae*).<sup>7,8</sup>

## EPIDEMIOLOGY

Brucellosis presents two epidemiologically different profiles (Table 41-1):

1. In developed countries, brucellosis is typically an occupational disease in abattoir workers,<sup>9</sup> butchers, veterinarians, and farmers, usually affecting adult men (and occasionally family members), who become infected through the skin and conjunctiva. It is usually caused by *B. abortus*.<sup>10,11</sup>
2. In endemic countries, principally three important regions, infections are associated with *B. melitensis*. These regions include Mediterranean countries (Spain, Portugal, Italy, and Greece), Middle Eastern countries (Iran, Iraq, Kuwait, Saudi Arabia, Israel, and Jordan),<sup>12,13</sup> and Latin American countries (Peru, Argentina, and Mexico).<sup>12,14–18</sup> In these regions, males and females are equally infected and 20% to 25% of cases are children. Infections are typically acquired through the consumption of dairy products, especially nonpasteurized goat cheese and untreated milk.<sup>19,20</sup>

Recently, two cases of *B. melitensis* were reported in Bangkok, which signifies the re-appearance of brucellosis in Thailand after 36 years.<sup>21</sup>

Some outbreaks, including those in family groups, have been reported from common sources, often from contaminated edible products.<sup>22–28</sup> *B. melitensis* may symptomatically infect up to 50% of family members.<sup>20,29</sup> A Saudi Arabian study evaluated household members of patients with acute brucellosis through serological screening; two members or more tested positive in 42% of the families. The risk factor in these families was raw milk ingestion.<sup>30</sup> The lowest attack rates are in young children, probably related to food habits rather than to immunity. Evidence does not support human-to-human transmission, except in rare cases of infection via bone marrow transplantation,<sup>31</sup> blood transfusion, and a possible case of transmission to a sexual partner via the organism in semen.<sup>32</sup> Women develop more severe brucellosis<sup>20,32,33</sup> with more articular involvement<sup>29</sup> and more severe thrombocytopenia<sup>34</sup> with *B. melitensis* infections. The other two *Brucella* organisms of human importance are *B. abortus*, whose reservoir is cattle, and *B. suis*, which is an enzootic disease in swine. *B. canis* has infected only a few dog breeders.<sup>35,36</sup>

As in other developed areas, in the United States, *B. abortus* has been the most frequent cause of brucellosis, as noted in reports from Iowa and Texas.<sup>9,37,38</sup> Since 1986, the Centers for Disease Control and Prevention (CDC) has listed brucellosis as a notifiable disease of low frequency, with fewer than 50 human cases per year, most likely because of the bovine brucellosis eradication program. More than 60% of U.S. cases

**Table 41-1** *Brucellosis: Epidemiologic and Clinical Differences*

	<i>Brucella abortus</i>	<i>Brucella melitensis</i>
Principal reservoir	Cattle	Goats
Transmission	Worker's disease: veterinarians, farmers, butchers	Consumption of nonpasteurized goat cheese
Age	Adults 20–45 yr	All ages, 25% children
Sex	>95% male	50% female
Geographic location	United States	Arabian countries; Latin America: Peru, Mexico, Argentina; Mediterranean countries: Spain, Italy, France, Greece, Portugal
Pathogenicity	Low	High
Subclinical-clinical case ratio	8:1	<1:1
Clinical pattern	Mild disease; no chronic form; mortality <0.1%	More severe form, frequent relapses: chronic form 1%–5%; mortality 1%
Outbreaks	Rare	Frequent in the United States with imported dairy products
Family cases	Rare	Occasional

occur in Texas and California, and only 5% to 10% are recognized and/or reported.<sup>39</sup> *B. melitensis* has also been reported in travelers to endemic areas where the use of antacids and H<sub>2</sub>-receptor inhibitors has been considered as a risk factor, in addition to the consumption of “typical” local food prepared with unpasteurized cheese or milk.<sup>40</sup>

Brucellosis is an emerging disease in travellers to Latin America, the Middle East, and the Mediterranean coast, especially among people who receive antacids or eat unpasteurized cheese.<sup>41</sup> *Brucella* is one of the most infectious bacteria to laboratory personnel through aerosols.<sup>41,42</sup> However, with the new biohazard precautions and the use of biologic safety hoods, laboratory infections have become infrequent.<sup>43,44</sup>

## CLINICAL MANIFESTATIONS

It is useful to stratify the different clinical presentations of brucellosis due to *B. melitensis*.<sup>45</sup> However, it is less helpful in the evaluation of patients with *B. abortus* or *B. suis* infections, because chronic or recurring forms are infrequent.

### Acute Form (Classical Febrile Brucellosis)

In acute *B. melitensis* infections, patients typically present with evening fever (100°F or greater), with profuse or patchy sweating, malaise, headache, and weight loss (3 to 10 kg in 1 to 2 weeks). Half of these patients have arthralgias and one-third have arthritis, often with myalgias and back pain.

Mild anemia, leukopenia, and hepatic involvement are frequent,<sup>46–50</sup> but psychiatric and urologic complications are rare. Constipation is common in endemic brucellosis; however, patients may present with diarrhea and fever, especially travelers from developed countries.

### Relapsing or Undulant Form (Malta Fever)

This is the “classical pattern” described by Bruce<sup>1</sup> and is observed after 2 months with the disease. In the preantibiotic era, 75% of patients developed this form, with rare cases persisting beyond 1 year. This form represents 25% to 30% of cases in endemic areas and usually reflects incomplete treatment, failure of standard treatment, or lack of a proper initial diagnosis and therapy.

Hepatic involvement and arthritis are common, as is a mild depressive mood, and occasionally uveitis and orchiepididymitis in young males.<sup>51</sup> This form may also present as a fever of unknown origin (FUO).<sup>52</sup>

### Chronic Brucellosis

Two patterns of chronic brucellosis (lasting more than 1 year) may be seen. The first is a cyclic course with back

pain, arthralgias, sweating, and depressive mood. This pattern is very similar to the chronic fatigue syndrome and occurs more frequently in women, especially women older than 40 years of age.

The second chronic form is localized brucellosis: spondylitis or uveitis (or episcleritis) without fever or systemic symptoms. This form is frequent in adults (representing 5% to 10% of cases in endemic areas), affects both sexes equally, but is rare in children.

In addition to the preceding clinical forms, the following sections detail complications (often localized) that may be seen (listed in order of decreasing frequency).

### Arthritis

The frequency of arthritis depends on the criteria used and whether the series is prospective or not; some have counted arthralgias as arthritis. Several forms of arthritis are listed in Table 41-2.

*Peripheral arthritis* is the most common presentation, affecting young adults and children; most cases involve monarticular arthritis in the knee or hip.<sup>45,53</sup> However, some patients have polyarthritis and other rheumatoid-like syndromes. Peripheral arthritis likely involves two pathogenic mechanisms: (1) *Reactive arthritis* is associated with poly- or pauciarticular involvement, where *Brucella* is not isolated from the joint. This form is associated with high circulating immune complex levels,<sup>54</sup> has a good prognosis, and often remits spontaneously.<sup>13,55–57</sup> (2) Alternatively, *infectious monarticular arthritis* can occur in which the organism is able to be isolated from synovial fluid when the proper culture medium is used. The prognosis depends on appropriate antibiotic treatment. Low levels of lactate in synovial fluids have been reported to be associated with the isolation of *Brucella* from the joint.<sup>58</sup> Even biopsy of the synovial fluid does not distinguish between reactive and infectious arthritis (both are exudative and inflammatory); only the clinical pattern and the appropriate culture can define which process is involved. More unusual forms include sternoclavicular arthritis<sup>59,60</sup> and extra-articular rheumatism (tendinitis, bursitis, and fibrositis) seen in approximately 10% of adult women.

*Sacroileitis* is the second most frequent articular lesion.<sup>44,61</sup> It is usually unilateral, more frequent in young adults, seen in both sexes, and often associated with pain on movement (Lasègue’s sign). The bone scan is helpful in diagnosis.

*Spondylitis* occurs in 5% to 10% of patients with brucellar arthritis.<sup>45,53,62</sup> A Hungarian study noted the association of human leukocyte antigen (HLA)-B27 with brucellar spondyloarthritis<sup>63</sup>; however, this association is less impressive in our Peruvian familial studies of brucellar arthritis.<sup>64–66</sup> Narrowing of the disk space (diskitis) is the earliest sign; however, the presence of lytic and blastic lesions and the erosion of the anterosuperior

**Table 41-2** Arthritis in Brucellosis Related to Age and Clinical Form

Brucellosis Clinical Form	Brucellar Arthritis	Peripheral Arthritis	Sacroileitis	Spondylitis	Age
Acute	20%–35%	Frequent	Frequent	Rare	Children, young adults
Subacute	25%–40%	Common	Frequent	Common	Young adults, children
Chronic	40%–60%	Rare	Rare	Frequent	Mainly >40 yr

**Table 41-3** Differential Diagnosis of Tuberculous versus Brucellar Spondylitis

	<b>Tuberculous Spondylitis</b>	<b>Brucellar Spondylitis</b>
Age	Young adults (20–40 yr)	>40 yr old
Sex	More common in males	Slightly more frequent in females
Main localization	Dorsal	Lumbar
Two or more vertebrae	<10%	20%–30%
Paravertebral abscess	Very common	10%–20%
Radiography	Lytic lesion (rare, blastic)	Lytic and blastic lesion
Sequelae (gibbus or humpback deformity)	Common	Rare

part of the vertebral body (“parrot peak”) is the most characteristic presentation.<sup>67–69</sup> This form is rare in children; most patients are older than 40 years of age. Important differential diagnostic considerations are other infectious spondylitis such as tuberculous (Table 41-3) and *Staphylococcus aureus* spondylitis. *S. aureus* spondylitis is painful and presents with fever, a symptom less commonly seen with tuberculous spondylitis and occasionally in brucellar spondylitis, given that it is a late complication. A recent report describes an Italian couple whose only symptom was spondylitis-generated pain.<sup>70</sup> Their pain was exacerbated by lying down, which differs it from osteoarthropathic pain, which improves with rest. In addition, brucellar spondylitis, with its diskitis and reduction of the intervertebral space, must be distinguished from neoplastic metastasis that affect vertebral bodies.

### Hepatitis

Although the presence of hepatomegaly is frequent (50% to 70%) and increased alkaline phosphatase is common, clinical hepatitis is less frequent and is detected in approximately 3% to 6% of adults. In the case of *B. melitensis*, the finding of granulomas is infrequent in the United States,<sup>71</sup> but we have noted that granulomatous hepatitis confirmed by electron microscopy is common in Latin America and may occur in association with the development of a cell-mediated immune response.<sup>49,50</sup> Sometimes more severe forms of hepatitis with bone and hematologic changes are seen.<sup>11,43,72,73</sup> In the 1940s, severe hepatitis was a common cause of death, as reported in an autopsy study.<sup>74</sup>

### Hematologic Involvement

Mild anemia and leukopenia with lymphocytosis are common in uncomplicated brucellosis.<sup>75–77</sup> We have found that the degree of lymphopenia is correlated with the severity of brucellosis.<sup>77</sup> Bone marrow aspiration frequently shows iron deficiency (up to 35%, even in males); the absence of iron has been associated with more aggressive courses in animals,<sup>48</sup> a finding that could explain the greater severity of brucellosis in women than in men.<sup>29,33,34</sup> While three of four males studied had normal values of iron deposits in bone marrow, only 6 of 18 females had normal iron stores ( $P < 0.02$ ). We also have found

severe thrombocytopenia to be associated with brucellosis in 6 of 485 males and 21 of 605 females ( $P < 0.05$ ).<sup>34</sup> Severe thrombocytopenia may require steroid therapy, and in some patients with persistent thrombocytopenia after 2 months of treatment and proven bacteriologic cure, splenectomy may be necessary.<sup>34,78</sup>

Rare complications of brucellosis include Evans's syndrome,<sup>76,77</sup> with pancytopenia and cytophagocytosis,<sup>79–82</sup> which can be confused with malignant histiocytosis. Pancytopenia is caused by granulomas in bone marrow.<sup>47</sup> Severe thrombocytopenia may cause fatal central nervous system (CNS) hemorrhage.

### Neurologic Involvement

Neurobrucellosis is reported in 1% to 5% of adults, but is a rare complication in children.<sup>83–86</sup> It usually involves meningitis or encephalitis. The cerebrospinal fluid (CSF) is similar to that in other chronic meningitides with increased lymphocytes and protein; CSF cultures are positive in 10% to 20% of cases.<sup>87</sup> The clinical pattern is characterized by fever, headache, neck rigidity, and altered consciousness. In contrast to tuberculous meningitis, the cranial nerves are usually not involved in neurobrucellosis. Guillain-Barré syndrome can be seen in young adults with acute brucellosis; brain abscesses are rare.<sup>88–92</sup> The CNS may also be involved in *Brucella* endocarditis or from bleeding in severe thrombocytopenia; both are associated with a poor prognosis.

### Other Complications

One of the risk factors for travelers from developed countries to endemic areas is the use of antacids or H<sub>2</sub>-receptor antagonists. In these patients, gastrointestinal symptoms are frequent, mainly subacute diarrhea (although among residents of endemic areas, constipation is more common).<sup>40,93</sup>

*Brucella* endocarditis can occur in a previously normal aortic valve (50% to 70% of *Brucella* endocarditis), and it remains the leading cause of death in brucellosis.<sup>83,84</sup> When the patient recovers, the valve becomes calcified. Despite some reported success with medical treatment alone, most experts recommend valve replacement and 2 to 3 months of antibiotic therapy.<sup>94–96</sup>

In chronic brucellosis (with *B. melitensis*), psychiatric disorders are common: These include “brucellar neurasthenia,” chronic fatigue, amnesia, and depression.<sup>97,98</sup> In the preantibiotic era, suicide was one of the causes of death.<sup>99,100</sup> Symptoms often persist after the infection is cured; antidepressant or other symptomatic therapy may be required for 3 to 6 months.

### Eye Involvement

Eye involvement is an unusual complication that may occur in subacute or chronic forms of brucellosis. Anterior or posterior uveitis is the most common ocular manifestation of *Brucella* infection.<sup>101,102</sup> Panuveitis often results in loss of vision.<sup>103–106</sup> Other ocular lesions include papilledema, optic neuritis, and episcleritis.<sup>105–109</sup> In patients without proper treatment, secondary glaucoma, cataracts, retinal detachment, and phthisis bulbi have been reported.<sup>101–104</sup>

## Pulmonary Involvement

Pulmonary involvement constitutes an important complication in the bioterrorism era. In an extensive review of 450 brucellosis patients in Greece, 31 had a respiratory pathologic findings at the time of diagnosis. Patients mainly had lobar pneumonia and presented with an interstitial pattern in chest x-rays.<sup>110</sup>

## Brucellosis in Children and Pregnancy

Brucellosis produces mild to moderate disease in children, but the chronic form is rare. Relapses in children are usually due to incomplete treatment. Hepatitis and arthritis are often seen in children. The arthritis is usually peripheral, but hip or knee arthritis may be seen.<sup>12,15,111–113</sup>

Brucellosis during pregnancy is associated with poor fetal prognosis with a high rate of abortion, miscarriage, prematurity, and fetal death.<sup>17,83,114</sup> In a recently extensive case series from Saudi Arabia that included pregnant women with brucellosis, the incidence of spontaneous abortion in the first and second trimesters was 43%, whereas the incidence of intrauterine fetal death in the third trimester was 2%.<sup>115</sup> The study also reported the beneficial effect of prompt treatment with cotrimoxazole or cotrimoxazole/rifampin over fetal prognosis.<sup>115</sup> In another

Peruvian series of pregnant women with brucellosis, early treatment with rifampin for 6 weeks plus an aminoglycoside greatly improved the fetal prognosis.<sup>116</sup> A few cases of congenital brucellosis have been reported, but early diagnosis and proper treatment should prevent most congenital infection.

## HIV and Brucellosis

Regarding brucellosis among HIV patients, a Spanish series reported 12 cases properly diagnosed (8 with culture positive to *Brucella* spp. and 4 with high anti-*Brucella* antibody titers, with a median CD4 count of 544 (136–1006). In this series, the clinical pattern and response to therapy was similar to what is expected in non-HIV patients: 2 of 12 had initial relapses, although no additional microbiologic relapses were seen in 18 months of followup.<sup>117</sup> It should be noted that there are other reports that have described more frequent relapse in HIV patients.<sup>118,119</sup>

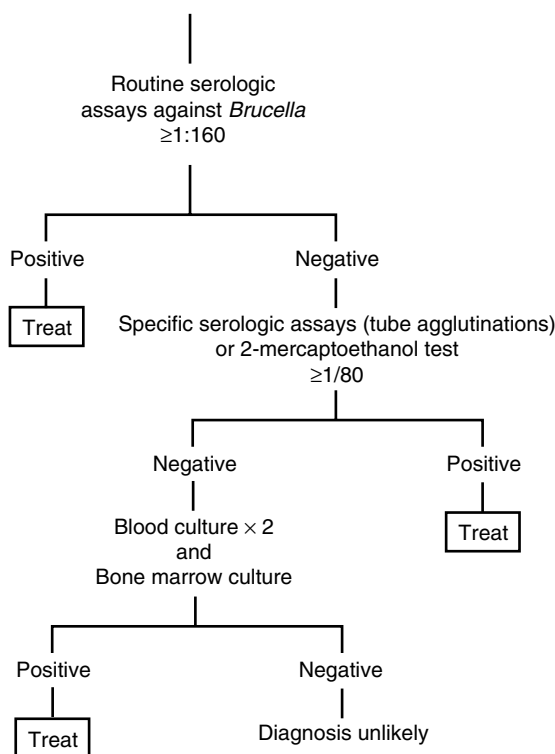

## PATHOGENESIS AND IMMUNITY

*Brucella* infections are likely acquired via small or subclinical skin abrasions, conjunctival inoculation, or perhaps less commonly via the respiratory route. *B. melitensis* is more

### SUBACUTE BRUCELLOSIS

Suspected because of: (a) a previous diagnosis of brucellosis with incomplete treatment or (b) an appropriate epidemiologic background, including:

1. Travel to Latin America, the Mediterranean, or Arab countries
2. Consumption of unpasteurized cheese
3. Laboratory employment (bacteriology division)
4. Veterinarian or farm work

**FIGURE 41-1** Algorithm for the diagnosis and treatment of subacute brucellosis.

acid- and serum-resistant and is likely acquired frequently via oral ingestion. The 2- to 3-week incubation period likely involves invasion, perhaps analogous to typhoid fever, with multiplication in macrophages since the organism is able to survive intracellularly. Its smooth lipopolysaccharide (LPS) appears to be responsible for the resistance of *Brucella* to serum.

The tendency of *B. abortus* to localize in placental tissue in cattle may well relate to the enrichment of placental tissue with erythritol, which may stimulate the growth of this organism.<sup>120</sup> Furthermore, unlike *B. melitensis* and *B. suis*, which tend to cause abscesses in experimental animals, *B. abortus* tends to cause granuloma formation in mice.<sup>121</sup> Immune responses, initially immunoglobulin M (IgM) then proceeding to IgG, clearly do not provide full protective immunity, since relapsing disease can occur. The role of cell-mediated immunity is suggested by the formation of granulomas and likely determines the characteristic recovery from and partial resistance to subsequent reinfection.

## DIAGNOSIS

Since the protean clinical and routine laboratory manifestations are not specific to brucellosis, a thorough history of occupation, travel, and consumption of unpasteurized milk or milk products is key to making the diagnosis (Figs. 41-1 and 41-2). Although it requires biosafety level 3 precautions, the isolation of *Brucella* provides a definitive diagnosis. The best procedure is bone marrow culture,<sup>122,123</sup> with a yield of 92% (vs. 70% with two blood cultures;  $P < 0.001$ ) and with faster growth (4.32 days vs. 6.65 days;  $P < 0.01$ ) in our prospective study. The best medium, Ruiz-Castañeda,<sup>122,124</sup> was modified by Carrillo through the addition of sodium polyethylene sulfonate (SPS) and cysteine. With the new DuPont Isolator and Bactec techniques, the isolation is improved.<sup>125,126</sup> Bone marrow culture is especially important in difficult clinical cases with epidemiologic suspicion of brucellosis, and when serologic tests are negative (as seen in relapsing uveitis,<sup>104</sup> unexplained fever,

or with hematologic abnormalities).<sup>3</sup> However, in routine evaluations, the diagnosis of brucellosis is usually made by serology<sup>124,127</sup>; in a large series in the United States, only 17% of cases had bacteriologic isolation.<sup>37</sup>

In Spain and Peru, the rose bengal test remains an inexpensive, sensitive, and specific test; however, it is not useful in follow-up of patients or in diagnosing relapses.<sup>14,120,128,129</sup> In these cases, 2-mercaptoethanol (2-ME) is used to detect IgG antibody.<sup>129,130</sup> However, well-standardized *Brucella* antigen (usually from the smooth, cross-reacting *B. abortus* strain, which may miss rough *B. canis* infections) and dilution to exclude false-negative prozone effects are key to the diagnosis. Antigens often used in "febrile agglutinins" are frequently nonspecific with cross-reactions from cholera, tularemia, or *Yersinia* infections. Polymerase chain reaction (PCR) methods using ribosomal RNA are under development.<sup>131</sup> In Germany, they have lately been using PCR enzyme-linked immunosorbent assay (ELISA) and real-time PCR assays with promising results.<sup>132</sup>

## BRUCELLA AS A BIOTERRORISM AGENT

*Brucella* is listed as a potential agent for a biologic attack by the CDC. *Brucella* spp. carries risk mainly because its aerosols are easy to prepare and disseminate. Even 10 to 100 bacteria can produce human disease, and it poses substantial risk for laboratory acquired infection.<sup>133-135</sup> In the laboratory, attack rates can be as high as 30% to 100% depending on the inoculum size and the worker's position. *Brucella* needs to be handled with the biosafety guidelines of a level 3 organism.<sup>136-138</sup> The strategy chosen for combination antibiotic prophylaxis and serologic follow-up of exposed workers is provided in a recent report from Quebec after a large exposure of workers to *B. melitensis*.<sup>139</sup> A model to evaluate the economic impact and potential medical care in a brucellosis postattack intervention was reviewed with emphasis on pulmonary aerosol use.<sup>140</sup>

## TREATMENT AND PROGNOSIS

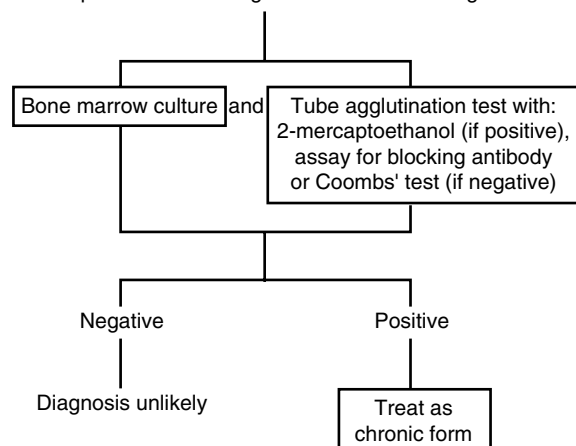

Although several antibiotics have in vitro activity against *Brucella*, effective agents must be active intracellularly, produce a rapid decrease in fever, reduce or treat complications, and have a low rate of relapse. Because of the high rate of relapse with monotherapy, two antibiotics are usually recommended.<sup>88,141-144</sup>

The drug of choice is tetracycline because of its intracellular bactericidal activity against *Brucella*<sup>145</sup> and because it has a low rate of relapse and a large international experience showing its efficacy.<sup>146-149</sup> The gastrointestinal tolerance of tetracyclines is poor and there is interaction with milk, antacids, or meals. Doxycycline has fewer side effects and its twice-daily use after meals is well tolerated. However, patients should avoid sun exposure because it occasionally causes photosensitivity.

Doxycycline should be used in combination with another antibiotic (Box 41-1). The World Health Organization (WHO) recommends 6 weeks of the combination of doxycycline with rifampicin 600 to 900 mg/day.<sup>43</sup> Doxycycline for 6 weeks can also be combined with streptomycin (or netilmicin), one dose daily for 2 weeks, with good results.<sup>146,150,151</sup> However, rifampicin may increase the clearance of doxycycline and reduce the doxycycline half-life in serum (mainly in rapid acetylators)<sup>152</sup>;

### CHRONIC BRUCELOSIS SUSPECTED (at least one):

1. Chronic fatigue syndrome with epidemiologic background
2. Spondylitis with osteoblastic and osteoclastic lesions
3. Granulomatous uveitis or panuveitis
4. Depression with low-grade fever and arthralgias

**FIGURE 41-2** Algorithm for the diagnosis and treatment of chronic brucellosis.

**Box 41-1** Treatment of Brucellosis

Adults: Doxycycline\* PO 100 mg bid × 6 weeks plus rifampicin PO 600 to 900/day × 6 weeks or streptomycin or netilmicin IM once a day × 14 days  
 Children ≥ 7 years old: Same treatment as adults (only 4 weeks)  
 Children < 7 years old: Rifampicin 10 mg/kg/day × 4 weeks plus streptomycin or netilmicin once a day × 14 days or co-trimoxazole × 4 weeks  
 Pregnancy: Rifampicin 600 mg/day × 6 weeks plus streptomycin or netilmicin once a day × 14 days

\*In the chronic form, a prolonged course of doxycycline 100 mg/day × 6 weeks more may be indicated along with antidepressant drugs as needed.

frequent relapses have been seen with this combination. A meta-analysis from five Spanish trials shows a significant rate of relapse with rifampicin plus doxycycline in comparison with streptomycin and doxycycline.<sup>35</sup> In a study in Spain, azithromycin and gentamicin were used to treat 10 brucellosis patients; the cure rate was 7 out of 10 but the relapse rate was high. These results do not favor the use of azithromycin in brucellosis.<sup>153</sup> In children, the relapse rate is low when receiving 4 weeks of treatment.<sup>12,15</sup>

In pregnant women and children younger than 7 years of age, tetracyclines are contraindicated. Some studies have described the use of rifampicin in combination with aminoglycoside (or co-trimoxazole).<sup>12,15,17,83,145</sup>

**PREVENTION AND CONTROL**

Because brucellosis is a zoonosis, the best control measure is prevention, with pasteurization of dairy products and use of gloves and masks by veterinarians and farmers. In the laboratory, careful adherence to safety guidelines and precautions is imperative.<sup>145</sup>

As a zoonosis in domestic animals, brucellosis is prevented by serologic testing and elimination of infected cattle and by routine pasteurization of milk. In addition, immunization of calves with a *B. abortus* strain 19 vaccine and of goats with a *B. melitensis* strain rev-1 vaccine is helpful. Some have used a live attenuated *Brucella* vaccine in persons at high risk, but this is not widely available. Improved animal husbandry and use of animal control measures and milk pasteurization have substantially reduced brucellosis in many areas.

# Plague

DAVID T. DENNIS  
PAUL S. MEAD

## INTRODUCTION

### Definition

Plague in humans is a severe febrile illness caused by the gram-negative bacillus, *Yersinia pestis*. Historically, it is synonymous with catastrophic epidemics. *Y. pestis* is maintained in nature as a zoonotic infection of rodents and their fleas in scattered foci in large areas of Asia, Africa, and the Americas. It is an incidental infection of humans and mammals other than rodents. Humans acquire infection most often by the bite of rodent fleas, occasionally by handling or ingesting infected animal tissues, or by inhaling contagious airborne particles. The vast majority of cases of human plague now occur in underserved Third World populations where sanitation is poor and persons live in close association with rodent reservoirs of infection. The principal clinical forms of plague are bubonic, septicemic, and pneumonic. Bubonic (lymphadenitic) plague accounts for 85% or more of primary plague cases. Septicemic and pneumonic plagues occur most often as secondary complications of bubonic plague, but may arise directly from primary infections. All forms of plague are curable if they are diagnosed and treated early. However, delays in treatment can rapidly lead to potentially fatal overwhelming infection and endotoxemia. Although plague has a high epidemic potential, preventive steps can be taken to reduce risks of exposure, and outbreaks can be readily halted using standard public health measures. Cases should be reported to health authorities immediately so that appropriate investigative and control measures can be implemented without delay. Reporting and control of the disease is mandated by national and international health regulations. Recently, concern has been raised over plague as a potential weapon of terrorism; *Y. pestis* has been classified as a Category A select agent subject to federal laws governing its management and transport. Medical and public health preparedness and response plans have been developed to counter the threat of its potential misuse.<sup>1,2</sup>

### History

Three pandemics of plague have been recorded. In the Justinian pandemic (circa 542–767 AD), it is thought that plague moved from upper Egypt to the Mediterranean and spread from there to Europe and Asia Minor, ultimately

causing an estimated 40 million deaths. The second plague pandemic began in Central Asia early in the 14th century, caused epidemics in China and India, and moved along caravan routes to the Near and Middle East. Entering Messina by ship in 1347, plague swept swiftly through Europe and the British Isles, receiving the epithet “Black Death.” Medieval plague killed a quarter or more of the affected populations at its height and was followed by successive epidemics in the European region over the next several centuries. The last global surge of plague, the third (modern) pandemic, arose in the latter half of the 19th century in Yunnan Province, China, struck Hong Kong in 1894, and spread from there by rat-infested steamships to port cities throughout the world, including several in the United States.<sup>3–5</sup> Within 30 years of its appearance in Hong Kong, the third plague pandemic had resulted in 26 million human cases and more than 12 million deaths, most of them in India.<sup>3</sup>

The plague bacillus was first identified in Hong Kong in 1894 by Alexandre Yersin, who isolated the organism from enlarged lymph nodes (buboes) of plague victims.<sup>6</sup> In 1898, Paul-Louis Simond, a French scientist sent to investigate epidemic plague in Bombay, identified the plague bacillus in the tissues of dead rats and subsequently proposed that the organism was transmitted from rat to rat, and from rats to humans by rat fleas.

After 1900, the global spread of plague was limited by regulations that controlled rats in ports and imposed inspection and rat-proofing of ships. *Y. pestis* did, however, become newly established among urban and rural rodent populations in many previously unaffected areas of the Americas, Europe, Africa, and Asia, resulting in scattered zoonotic foci that still exist throughout the world today.<sup>7,8</sup> In San Francisco, between 1900 and 1908, major outbreaks of rat-borne plague killed more than 200 persons. By 1908, plague was epizootic in ground squirrels in counties surrounding the city,<sup>5</sup> and in subsequent years spread to wild rodent populations throughout California and other states in the western third of the country. The last outbreak of urban plague and of person-to-person pneumonic transmission in the United States occurred in a slum area of Los Angeles in 1924–1925.

By the middle of the 20th century, cities in the United States and elsewhere had enforced higher sanitary standards and building codes, effective insecticides and rodenticides had become widely available, and several classes of antibiotics had been shown to be efficacious in treating plague. Most human plague since then has been sporadic and rural in distribution. Outbreaks have been relatively slow to develop and readily controlled by a combination of surveillance, early diagnosis and treatment, and flea and rat suppression.<sup>9</sup> The major exceptions to this generalization were the large rat-borne plague epidemics that occurred from 1962 to 1975 in war-torn Vietnam and in the 1990s in Madagascar.<sup>6,10</sup>

Plague is one of the three diseases (plague, cholera, yellow fever) subject to quarantine under World Health Organization (WHO) international health regulations.<sup>11</sup> In 1994, articles of these regulations were used to prevent potential spread of plague from India after a reported outbreak of pneumonic plague there evoked local panic and an exaggerated international response to the perceived health emergency.<sup>12,13</sup>

## AGENT

### General Microbiology

*Y. pestis* is a nonmotile, nonsporulating, gram-negative coccobacillus in the family Enterobacteriaceae.<sup>4,14</sup> It is microaerophilic, oxidase- and urease-negative, non-lactose-fermenting, and biochemically unreactive. The organism is nonfastidious and is highly infective to laboratory rodents. *Y. pestis* grows slowly but well on a wide variety of common media (e.g., brain-heart infusion broth, sheep blood agar, chocolate agar, and MacConkey agar). Routine specimens can be safely handled under BSL-2 procedures, but manipulation of isolates requires BSL-3 measures to adequately protect laboratory workers.<sup>14</sup> Growth occurs across a wide range of temperature (4°C to 40°C) and pH (5.0 to 9.6), but is optimal at 28°C and pH 7.4. Incubation at 37°C for 24 hours on agar yields pinpoint, transparent colonies that are easily overlooked, especially if there is contamination of the culture by other bacteria. At 48 hours, colonies are typically gray, 1 mm to 2 mm in diameter, and have an irregular “hammered metal” appearance when viewed under magnification. In broth, *Y. pestis* grows in flocculent clumps, typically attached to the sides of the tube in downwardly projecting stalactite forms that leave a clear broth. With polychromatic stains such as Wayson, Wright, or Giemsa, plague bacilli from clinical specimens demonstrate a characteristic bipolar appearance resembling closed safety pins (Fig. 42-1). Although *Y. pestis* is not truly encapsulated, it produces an envelope that contains the unique fraction 1 (F1) glycoprotein surface antigen.

Decoding of the entire genome of the plague bacillus shows that it only recently evolved from *Y. pseudotuberculosis*.<sup>15,16</sup> It is highly adapted to rodents and their fleas and does not long persist outside them. In the environment, it is rapidly killed by temperatures above 40°C and by desiccation.

### *Y. pestis* Virulence Factors

*Y. pestis* expresses several virulence factors that are important for its survival in rodents, humans, and fleas.<sup>4,17–19</sup> Most genes encoding these virulence factors reside on three plasmids, *Pst* (9.5 kb), *Lcr* (approximately 70 kb), and *pFra*

(approximately 110 kb). The *Pst* plasmid encodes a temperature-dependent plasminogen activator (Pla) and a bacteriocin (pesticin). The plasminogen activator, a bacterial surface protease, is important for survival of *Y. pestis* in fleas. This protease facilitates the formation of a bolus of blood and aggregated bacteria in the flea midgut, which blocks the flea's proventriculus and leads to regurgitation of infective material when the “blocked” flea attempts to feed (see Epizootic Plague). Pesticin promotes iron uptake by *Y. pestis*.

The low calcium response plasmid (*Lcr*) encodes gene products active in low calcium environments. The products include various outer surface proteins (Yops) and a soluble V antigen, thought to be essential to *Y. pestis* survival in macrophages. Factors associated with the approximately 70-kb plasmid inhibit the production by macrophages of interferon-gamma (IFN- $\gamma$ ) and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ).

The *pFra* plasmid contains genes for the fraction 1 (F1) envelope glycoprotein antigen and a murine exotoxin. F1 antigen is produced only by organisms growing at 30°C or greater. *Y. pestis* strains expressing F1 antigen are able to resist phagocytosis in the absence of opsonizing antibodies. The murine toxin (Ymt) is highly toxic to mice and rats, but is not known to be toxic in humans. In the flea midgut, Ymt (recently recognized to be phospholipidase D) plays a critical role in protecting *Y. pestis* from a cytotoxic digestion product of blood plasma. The emergence in *Y. pestis* of the single responsible gene (*ymt*) did, by adapting the bacillus to fleas, radically separate the natural history of the plague bacillus from that of the enteropathogenic *Yersinia* spp.<sup>20</sup>

Chromosomally encoded virulence factors include a lipopolysaccharide endotoxin and a factor controlling the absorption of exogenous iron. Endotoxin is responsible for complement activation and release of cytokines. When *Y. pestis* is grown on media with Congo red, a heme-analogue dye, iron absorption is indicated by pigment production. Strains that do not produce pigment have diminished virulence in mammals and are unable to induce blocking in the flea gut. Hemin storage locus (*hms*) products expressed in the low temperature (28°C or less) environment of the flea assist in forming blockages of the flea gut necessary for efficient transmission.<sup>18–20</sup> A chromosomally encoded product, the pH 6 antigen (Psa), inhibits phagocytosis of *Y. pestis* in mammals.

### *Y. pestis* Biotypes

*Y. pestis* isolates can be classified into biotypes based on their ability to ferment glycerol and reduce nitrate. Three biotypes have been associated with respective plague pandemics.<sup>21</sup> Relict populations of the Antiqua biotype are found in Africa, southeastern Russia, and Central Asia; the Mediaevalis biotype is found around the Caspian Sea; and the Orientalis biotype in Asia and the Western Hemisphere. Typing based on ribosomal gene characteristics supports these distinctions. Considering their adaptation to diverse ecologies worldwide, wild *Y. pestis* strains are quite uniform, although finer genomic analyses have recently demonstrated subtle and evolving differences.<sup>22,23</sup>

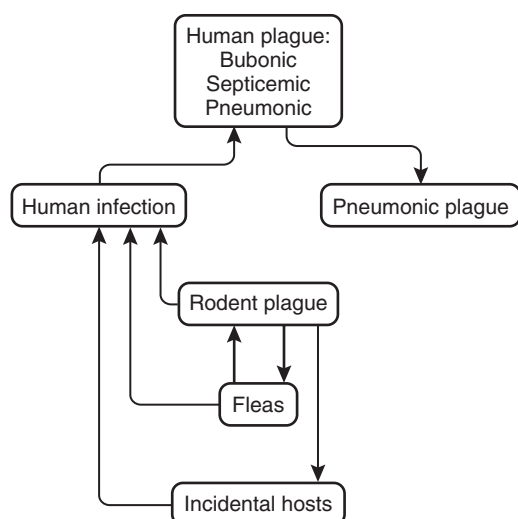

### *Y. pestis* Life Cycle

*Y. pestis* is a zoonotic infection that principally involves wild and domestic rodents, and their various flea species (Fig. 42-2).

**FIGURE 42-1** Peripheral blood smear from a patient with plague septicemia, showing characteristic bipolar-staining *Yersinia pestis* (Wright's stain, oil immersion).

**FIGURE 42-2** *Yersinia pestis* cycles, demonstrating the interrelationships of its rodent reservoir, flea vector, and incidental mammalian hosts, including humans. In the usual situation, *Y. pestis* is transmitted from rodent to rodent, and occasionally from rodent to human or other incidental mammalian host, by an infective rodent flea. Pet dogs and cats can bring infective rodent fleas into the home environment. Infection may be transmitted directly from rodent to rodent by cannibalism, and from infected animal to predator or to human by ingestion. Humans may also acquire infection by accidental percutaneous inoculation while handling contaminated tissues or fluids. Plague pneumonia can be transmitted from one person to another and, rarely, from cats to persons, by infective respiratory droplets.

Plague spreads from rodents to humans when humans intrude into the natural (wild) cycle, or when commensal rodents become infected and transmission is established in homes and other communal settings. Human-to-human transmission may result from close and unprotected exposure to persons with respiratory plague. Transmission from person to person by the human flea, *Pulex irritans*, is controversial. Studies of plague transmission in the 20th century suggest that spread by the human flea, if it occurs, is inefficient and uncommon; however, human fleas have been proposed as an important factor in the rapid spread of plague in Europe during the Black Death.

## EPIDEMIOLOGY

### Ecology

More than 200 species of mammals and 150 species of fleas have been found to be naturally infected with *Y. pestis*. However, few of these hosts are important for maintaining enzootic or epizootic life cycles, and fewer still pose a significant risk to humans. The natural history of *Y. pestis* is complex, and an understanding of the organism's ecology and life cycle is helpful in defining its epidemiology and designing control and prevention strategies (Box 42-1).<sup>7-9,24-26</sup>

### Enzootic Plague

In its natural reservoir hosts, infection with the plague bacillus is often unnoticed. This is characteristic of enzootic

## Box 42-1 Plague Foci

### North American Plague Foci

Wild rodent plague has been reported west of the 100th meridian in 17 contiguous western states and in some areas of adjacent Canada and Mexico.<sup>7,8,25</sup> The major plague sites are the southwestern focus, comprising mainly semi-arid grassland plateaus, foothills, and forested uplands of northeastern Arizona, most of New Mexico, southern Utah, and southern Colorado; the Pacific Coast focus, comprising mostly valley grassland, foothills, and the montane habitat of California and southern Oregon; the Great Basin focus, encompassing parts of Utah, Nevada, and southern Idaho; and the Rocky Mountain and northern focus, comprising mostly northern Colorado, Wyoming, and Montana.

The principal rodent hosts in the southwestern focus are various burrowing ground squirrels (*Spermophilus* spp.), prairie dogs (primarily *Cynomys gunnisoni*), wood rats (*Neotoma* spp.), antelope ground squirrels (*Ammospermophilus* spp.), deer mice (*Peromyscus maniculatis*), and related species. The major rodent hosts in the various niches of the Pacific Coast focus include *Spermophilus* spp., especially the California ground squirrel (*S. beecheyi*), the golden-mantled ground squirrel (*S. lateralis*), chipmunks (various *Tamias* spp.), deer mice and other *Peromyscus* spp., and voles (*Microtus* spp.). Other important hosts in the United States include various small ground squirrels (*S. elegans*, *S. beldingi*, and *S. townsendi*) in the Rocky Mountain and Great Basin regions, and the black-tailed prairie dog (*Cynomys ludovicianus*) in the Great Plains region. Epizootics of plague have recently occurred in urban tree squirrel (*Sciurus niger*) populations in cities along the eastern foothills of the Colorado Rocky Mountains, but pose a small risk to humans because these squirrels are parasitized by nonanthropophilic fleas.

Since 1950, a few cities in the United States have rarely been found to have *Y. pestis*-infected rats (e.g., Tacoma, San Francisco, Los Angeles, Dallas). However, no widespread epizootics or human plague cases have resulted, possibly because the rats have been infested with only small numbers of fleas or with flea species that are inefficient vectors of *Y. pestis*.

The principal fleas transmitting plague among wild rodent epizootic hosts in the United States include various ground squirrel fleas (*Oropsylla montana* [*Diamanus montanus*], *Hoplopsyllus anomalus*, *Thrassis* spp., *Opisocrostitis* spp., *Oropsylla idahoensis*), prairie dog fleas (*Opisocrostitis* spp.), wood rat fleas (*Orchopeas* spp.), and chipmunk fleas (*Eumolpianus eumolpi*).<sup>7,8,25</sup> *Or. montana* is the most important vector of *Y. pestis* to persons in the United States because it is a competent host that readily feeds on a wide range of rodents, and on other mammals, including humans.

Continued

**Box 42-1** Plague Foci—Cont'd**South American Plague Foci**

In South America, active enzootic plague foci exist in Brazil, Bolivia, Peru, and Ecuador, and have been described previously in Paraguay, Argentina, and Venezuela. *Y. pestis* infection in these foci has been variously found in commensal rats (*Rattus* spp.), cotton rats (*Sigmodon* spp.), rice rats (*Oryzomys* spp.), field mice (*Akodon* spp.), cane mice (*Zygodontomys* spp.), wild cavies, and domesticated guinea pigs (*Cavia* and *Galea* spp.).<sup>3,26</sup> Domestic guinea pigs are reared in homes for food in the Andean region and are considered a potential commensal risk of infection to humans; human plague outbreaks in the Andean region, including a recent extensive bubonic plague epidemic in northern Peru and a mixed bubonic/pneumonic plague outbreak in Ecuador, have been suspected to be associated in the domestic environment with infected guinea pigs as well as *R. rattus*. A previously active plague area in northeastern Brazil has been quiescent over the past 20 years. The various fleas that serve as principal vectors in South American foci are *X. cheopis* on *Rattus* spp. and *Polygenis* and *Pleochaetis* spp. on wild rodents. *Pulex irritans*, the human flea (which also parasitizes domesticated guinea pigs), has been implicated as a potential transmitter of plague to humans in some Andean outbreaks.

**African Plague Foci**

Widely scattered active plague foci exist in East and South Africa, including Democratic Republic of the Congo (previously Zaire), Uganda, Kenya, Tanzania, Zambia, Zimbabwe, Mozambique, Botswana, South Africa, Namibia, and Angola, and on the Indian Ocean island of Madagascar.<sup>3,7,26</sup> Less active foci exist in some northern Africa states (e.g., Libya, Algiers). The principal wild rodent hosts in Africa include gerbils (*Tatera* and *Desmodillus* spp.), swamp rats (*Otomys* spp.), various grass mice (*Arvicanthis* spp.), multimammate mice (*Mastomys* spp.), and commensal rats (*Rattus* spp.). One scenario describes plague in grassland gerbil populations spreading to multimammate mice in agricultural fields, and then to commensal rats in villages, resulting in human plague outbreaks. The principal flea vectors of wild rodent hosts are *Xenopsylla* and *Dinopsyllus* spp., while *X. cheopis* and *X. braziliensis* are the principal flea species involved in transmission among commensal rats and to man.

**Asian Plague Foci**

The most important Eurasian plague hosts are gerbils (various *Meriones* spp.) in Iran, Kurdistan, Transcaucasia, other areas around the Caspian Sea, and the plains of southeastern Russia and Khazakstan; marmots (*Marmota* spp.) in Central Asia, including mountainous Khazakstan, northeastern China, Mongolia, Manchuria, and in Transbaikalia; and ground squirrels (*Spermophilus* spp.) in Mongolia, northern-central China, the central Asian plains and steppes, and some areas around the Caspian Sea.<sup>3,7,26</sup> The primary flea vectors on gerbils are *Xenopsylla* and *Nosopsyllus* spp.; on marmots, various *Oropsylla*, *Rhadinopsylla*, and *Citellophilus* spp.; and on ground squirrels, *Citellophilus* and *Neopsylla* spp.

In India, the gerbil, *Tatera indica*, has been described as the principal wild rodent maintenance host.<sup>3,7,26</sup> Although it lives principally in open grassland sites in its natural state, it does invade agricultural fields and village peripheries. Other maintenance hosts include *Mellardia melitana*, various field mice, and palm squirrels (*Funambulus* spp.). The important commensal rat species are *Bandicota bengalensis*, *Bandicota indica*, *R. rattus*, and *R. norvegicus*. The primary vectors of plague in India are *X. cheopis* and *Xenopsylla astia*.

The principal rodent hosts in Myanmar, Vietnam, and Indonesia are *R. rattus* subsp. *diardii* and the Polynesian rat (*Rattus exulans*).<sup>3,7,26</sup> *R. rattus* subsp. *flavipectus* is an important host in southern China. *R. norvegicus* and the bandicoot, *B. indicus*, have been described as important hosts in Vietnam. The shrew, *Suncus murinus*, has been described as a possibly important host of plague in Vietnam and Indonesia. *X. cheopis* is the principal vector of plague in southern China, Myanmar, Vietnam, and Indonesia; *X. astia* (a less efficient vector) is also found on rats in Myanmar and Vietnam. *Stivalius cognatus*, a rat flea, is considered to be an important secondary vector of plague in Indonesia.

infections among rodents in remote, sparsely populated areas, such as the semiarid or arid grassland steppes of Central Asia and the savannahs of eastern Africa.<sup>7-9,25,26</sup> Fleas become infected by feeding on bacteremic rodents; although infection sickens or kills some enzootic hosts, most tolerate the infection and noticeable population die-offs do not usually occur. Although nonrodent mammals, such as predatory carnivores, do not serve as reservoirs of infection, they may contribute to the maintenance of zoonotic cycles by transporting infective fleas from one rodent population to another. Enzootic transmission generally places humans at a small risk of incidental infection, and associated cases are typically infrequent and sporadic.

**Epizootic Plague**

In epizootic plague, infection spreads rapidly among susceptible rodent populations transmitted by efficient flea

vectors (both rodents and fleas serve as amplifying hosts of *Y. pestis*).<sup>7,8,24-26</sup> Epizootics often result in die-offs of affected rodent populations and accelerated dispersal of their fleas. Spread of infective fleas to rodents living in close association with humans can pose a serious threat in residential areas. Prairie dogs are highly susceptible and sensitive epizootic hosts in the southwestern United States, and epizootics can quickly kill off colonies over wide areas, sometimes in close proximity to suburban developments.

Historically, urban epidemics and pandemic spread of plague have been linked to epizootics involving the commensal rodents *Rattus rattus* and *R. norvegicus*. The smaller, domestic, roof or black rat (*R. rattus*) is considered the most dangerous plague host. Since ancient times, this adaptable and clever rodent has lived in intimate domestic association with humans in Asia, the Middle East, and Africa. Its migration to Europe allowed the rapid spread of plague there during the medieval period.

Black rats live in homes, adjacent grain fields, granaries, stables and barns, warehouses, and other places where human activity provides them with ready shelter and food supplies. They travel easily with human cargo and baggage and have (with their complement of fleas) been the principal agents of noncontiguous (*per saltum*) spread of plague. In contrast, the Norway rat (*R. norvegicus*) was probably not an important host in the first two great pandemics and is thought to have first migrated from Asia to the Middle East and Europe as late as the 18th century, when it displaced the roof rat as the principal plague host in urban areas of Europe and elsewhere. *R. norvegicus* is larger and more aggressive than *R. rattus*; it is a burrowing rodent that lives around the foundations of buildings and frequents cellars, drains, sewers, alleyways, brush heaps, and refuse dumps. The quartet of *R. rattus*, *R. norvegicus*, *Y. pestis*, and the oriental rat flea, *Xenopsylla cheopis*, was responsible for the global spread of plague during the third (modern) pandemic. Densities of rats (measured by trapping success rates) and of fleas on rats (rat flea index) and *Y. pestis* infection rates of both are important surveillance measurements.<sup>7,9</sup>

Although domestic rats are the principal source of infected fleas in plague epidemics, they may not be able to sustain transmission of *Y. pestis* without reintroductions of the agent from the wild cycle. Recent investigations of bubonic plague in Maharashtra in western-central India suggested that local gerbils (*Tatera indica*) living in open, arid grasslands were the principal reservoirs of infection there, and that *Y. pestis* may have in part reached domestic *R. rattus* through intermediary populations of bandicoot rats (*Bandicota bengalensis*), which were numerous in adjacent croplands surrounding rural villages.<sup>27,28</sup>

The widely distributed oriental rat flea, *X. cheopis*, and the related species, *Xenopsylla braziliensis*, are efficient vectors of the plague bacillus between rats and are the most dangerous vectors to humans.<sup>3,7,9</sup> At ambient temperatures of 28°C and below, *Y. pestis* can multiply exponentially in the gut of these and a few other species of fleas and result in a clotted bolus of organisms that blocks the passage of further blood meals at the level of the foregut. The starving fleas avidly seek replenishing blood meals. Regurgitation by a “blocked” flea while it feeds enhances transmission of the plague bacillus to a new host. The ability of *Y. pestis* to cause blockage has recently been shown to be plasmid-mediated and dependent on a single gene change from *Y. pseudotuberculosis* (see *Y. pestis* Virulence Factors).<sup>19,20</sup>

### Incidental Animal Plague

A diverse range of wild and domestic mammals may become incidentally infected with *Y. pestis*, and humans can become infected when they have direct contact with their infected tissues or exudates, or when these incidental hosts transport rodent fleas into the domestic environment. Carnivores, especially felids, canids, and mustellids, are notable incidental hosts. Infected cats, in contrast to dogs, often become ill when infected with *Y. pestis* and have become an occasional source of human plague in the United States.<sup>29,30</sup> Lagomorphs (rabbits, hares) occasionally infect hunters and others who handle contaminated carcasses.<sup>31</sup> Ungulates, including antelope, deer, camels, and goats, can sicken and die from *Y. pestis* infection. Handling of carcasses of infected

goats, camels, and dromedaries, and ingestion of undercooked meat of these animals has been responsible for limited human plague outbreaks in northern Africa, the Middle East, and Central Asia.<sup>32</sup>

### Distribution of Plague

Plague foci are distributed throughout the world. From 1989 to 2003, 38,359 human cases (approximately 2500 cases a year) and 2845 deaths (7%) were reported to the WHO by 25 countries, as required by the international health regulations.<sup>33</sup> Nearly 80% of the cases were reported from the African region, 15% from Asia, and the remainder from the Americas. The countries that reported more than 1000 cases (from most to least) were Madagascar, Tanzania, Democratic Republic of Congo, Vietnam, Mozambique, Namibia, and Peru. The greatest recent emergence has occurred in eastern sub-Saharan Africa, especially in Tanzania and adjacent countries, and on the island of Madagascar. In Madagascar, recent outbreaks have occurred in coastal urban as well as rural highland areas.<sup>10,34</sup>

In the United States, in the period 1989 to 2003, there were 101 reported cases of plague (~7 cases per year) and 10 deaths (10%). In the United States, plague in animals occurs in 17 of the contiguous western states, in a region extending from the Pacific Coast to the Great Plains and central Texas. However, more than 80% of human cases occur in the southwestern states of New Mexico, Arizona, and Colorado, and approximately 10% in California.<sup>29,35</sup> In the United States, flea-borne plague is highly seasonal, occurring most often between May and October; winter plague cases are uncommon and most often arise from the handling of infected animals. In the tropics, plague incidence usually peaks in the cooler, moist months of the year.

### Risk Factors for Human Plague

The risk of plague varies with environmental circumstances and human behaviors, especially those that increase exposure to infective fleas. Low socioeconomic status is an important risk factor, because infestation by rats and their fleas is associated with poor housing and unsanitary conditions.

More than half of plague exposures in the United States are thought to occur in the general area of patients' homes.<sup>31</sup> This is particularly true in the Southwest, where homes in rural and semi-rural areas are often situated near habitats of highly plague-susceptible animals, such as prairie dogs, rock squirrels, and woodrats.<sup>7,8</sup> In the Sierra Nevada mountains of California and Nevada, epizootic plague in chipmunks and ground squirrels is a risk to visitors to public parks. Hikers, campers, and hunters throughout the western United States have a small but definite risk of exposure, especially in the warmer months of the year.

Plague can also be transmitted to humans by direct inoculation while skinning or otherwise handling infected rodents, rabbits and hares, domestic and wild felids, and coyotes.<sup>7,29,31</sup> Direct inoculation is associated with an increased risk of septicemia and a high fatality rate. In Mongolia and northeastern China, marmot hunting is the principal risk factor; further, when pneumonic cases arise, person-to-person transmission is facilitated in the cramped living quarters

(yurts) of these nomadic hunters. Pharyngeal plague may result from the ingestion of undercooked contaminated meat<sup>32</sup> and possibly by inhalation of infective respiratory droplets.

In the United States, relatively detailed information is available on human plague cases. Among 413 evaluable patients reported from 1960 to 2004, 333 (81%) presented with primary lymphadenitic (bubonic) plague, most thought to have arisen from infective flea bites; 64 (15%) of patients presented with primary septicemic plague, often after handling infected animal tissues; and 10 (2%) patients presented with primary pneumonic plague, 5 of whom had evidence of infective exposures from sick cats (CDC, unpublished data, 2005).

Following the extraordinary epidemics of pneumonic plague involving tens of thousands of cases in Manchuria in the period 1910–1926, pneumonic plague outbreaks around the world have occurred only sporadically, usually involving three or fewer generations of cases, and typically affecting family members, close friends, and care providers of pneumonic plague patients. The 1994 outbreak of reported pneumonic plague in Surat, India, probably involved fewer than 100 cases.<sup>13</sup> Small clusters of cases of pneumonic plague have more recently been reported from Ecuador, Madagascar, and northern India. Because respiratory spread of *Y. pestis* occurs by infective droplets, only persons with close respiratory exposure have a high risk of infection. Primary plague pneumonia is thought to possibly be more contagious than secondary pneumonia because it is more likely to produce copious watery sputum, and the patient may be mobile and expose a wider circle of individuals in the early stage of contagiousness.

## DISEASE

### Bubonic Plague

Bubonic plague is the prototypic plague illness.<sup>3,36,37</sup> The usual incubation period of bubonic plague is 2 to 6 days, occasionally longer. Illness typically begins with headache, fever of 38°C to 40°C, chills, myalgias, arthralgias, and a feeling of weakness. At the same time, or within 24 hours, the patient notices tenderness and pain in one or more regional lymph nodes proximal to the site of inoculation of the plague bacillus. The femoral and inguinal groups of nodes are most commonly involved, followed by the axillary and cervical nodes. Upper body sites may be relatively more involved in children than adults. The enlarging bubo(es) becomes progressively swollen, painful, and tender, sometimes exquisitely so. Typically, the patient guards against palpation and limits movement, pressure, and stretching around the bubo. The surrounding tissue often becomes edematous, sometimes markedly, and the overlying skin may be erythematous, warm, tense, and may desquamate (Fig. 42-3). Inspection of the skin surrounding or distal to the bubo sometimes reveals the site of a flea bite marked by a small papule, pustule, scab, or ulcer. Larger pustular lesions (furuncles or carbuncles), ulcers, and eschars may rarely occur and can be confused with those caused by tularemia or anthrax. The bubo of plague is distinguishable from lymphadenitis of most other causes by its rapid onset, extreme tenderness, accompanying signs of toxemia, and usual absence of cellulitis or obvious ascending lymphangitis.

**FIGURE 42-3** Patient with left inguinal and femoral buboes, demonstrating surrounding edema and overlying desquamation.

Treated in the uncomplicated state with an appropriate antibiotic, bubonic plague usually responds quickly, with disappearance of fever and resolution of other systemic manifestations over 2 to 5 days. Buboes often remain enlarged and tender for a week or more after treatment has begun and can occasionally become fluctuant. Without effective antimicrobial treatment, bubonic plague may progress to an increasingly toxic state of fever, tachycardia, lethargy leading to prostration, agitation and confusion, and, occasionally, convulsions and delirium. Mild forms of bubonic plague, called *pestis minor*, have been described in South America and elsewhere; in these cases, the patients are ambulatory, only mildly febrile, and have subacute buboes.

Plague patients typically have white blood cell counts of 12,000 to 25,000/ $\mu$ L with a predominance of immature polymorphonuclear leukocytes. Leukemoid reactions showing white blood cell counts as high as 50,000/ $\mu$ L<sup>3</sup> or more can occur.<sup>36</sup> Differential diagnostic possibilities for bubonic plague include streptococcal or staphylococcal adenitis, tularemia, cat scratch disease, mycobacterial infection, acute filarial lymphadenitis, chancroid and other sexually transmitted diseases that cause regional lymphadenitis, and strangulated inguinal hernia.

### Septicemic Plague

Septicemic plague is characterized by a rapidly progressive, overwhelming endotoxemia and dissemination of infection.<sup>38–40</sup> Primary septicemia occurs in the absence of an apparent regional lymphadenitis, and the diagnosis of plague is often not suspected until preliminary blood culture results are reported by the laboratory. Further, patients with sepsis often present with gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal pain, making a correct clinical diagnosis even more challenging.<sup>41</sup> If not treated early with appropriate antibiotics and aggressive supportive care, septicemic plague is usually fulminating and fatal. In the United States from 1960 to 2004, 19 of 64 primary septicemic plague cases were fatal, yielding a case-fatality ratio of 30%. The systemic inflammatory response syndrome (SIRS) may progress rapidly. Petechiae and ecchymoses are manifestations of disseminated intravascular coagulation (DIC). In later stages,

thrombi in the microvasculature of acral parts, such as tips of ears and digits, may result in gangrene of affected tissues. Refractory hypotension, acute renal failure, obtundation, and other signs of shock are preterminal events. Acute respiratory distress syndrome (ARDS) can occur in septicemic plague and be refractory to treatment.

Differential diagnostic possibilities include any other overwhelming systemic infection, including gram-negative sepsis with agents other than the plague bacterium, meningococcemia, and bacterial endocarditis. ARDS could be confused with other underlying conditions such as hantavirus pulmonary syndrome and severe acute respiratory syndrome (SARS).

## Pneumonic Plague

Pneumonic plague is a highly virulent form of plague.<sup>3,42</sup> The incubation period for primary pneumonic plague is 1 to 7 days, but most cases arise 3 to 5 days after exposure. The onset is most often sudden, with chills, fever, headache, body pains, weakness, dizziness, and chest discomfort. Cough, sputum production, increasing chest pain, tachypnea, and dyspnea typically predominate on the second day of illness and may be accompanied by hemoptysis, increasing respiratory distress, cardiopulmonary insufficiency, cyanosis, and circulatory collapse. In primary plague pneumonia, principally an alveolar process, the sputum is most often watery or mucoid, frothy, and blood-tinged, but may become frankly bloody. Chest signs in primary plague pneumonia may indicate localized pulmonary involvement in the early stage, with rapidly developing segmental consolidation before bronchopneumonia spreads to other segments and lobes of the same and opposite lung (Fig. 42-4). Liquefaction necrosis and cavitation may develop at sites of consolidation and may leave significant residual scarring.

Secondary plague pneumonia manifests first as an interstitial pneumonitis in which sputum production is scant, and the sputum is more likely to be inspissated and tenacious in character than the sputum found in primary pneumonic plague.

**FIGURE 42-4** Chest radiograph of a patient with primary plague pneumonia, showing extensive infiltrates in the right upper and right middle lobes.

In the United States from 1960 to 2004, 48 cases of secondary plague pneumonia and 10 cases of primary plague pneumonia were reported to the Centers for Disease Control and Prevention (CDC), with no known secondary transmission to contacts and an overall case-fatality rate of 40% (CDC, unpublished data, 2005). Observers of pneumonic plague in the early 20th century remarked on minimal auscultatory findings, the appearance of toxemia, and the frequency of sudden death, as compared to patients with other bacterial pneumonias.<sup>42</sup>

Differential diagnostic possibilities include other bacterial pneumonias such as mycoplasma pneumonia, Legionnaire's disease, staphylococcal or streptococcal pneumonia, tularemia pneumonia, and Q fever. Severe viral pneumonia, including hantavirus pulmonary syndrome and SARS, could be confused with plague.

## Meningeal Plague

Meningitis is an unusual manifestation of plague. In the United States, there were 18 (4%) meningitis cases among the total 413 evaluable plague cases reported to CDC from 1960 to 2004. Most cases were late complications of bubonic plague, and 14 patients (78%) survived. Although meningitis may be a part of the initial presentation of plague, its onset is often delayed and may be the result of insufficient antibiotic treatment of the primary illness.<sup>43</sup> Chronic, relapsing meningeal plague over periods of weeks and even months was described in the preantibiotic era. Plague meningitis presents as a typical bacterial meningitis, with fever, headache, altered mental status, meningismus, and a polymorphonuclear leukocytic pleocytosis.

## Pharyngeal Plague

Plague pharyngitis is an unusual condition and presents with fever, sore throat, and cervical lymphadenitis. In its early stages, it may be clinically indistinguishable from more common causes of pharyngitis.<sup>3</sup> Cervical or submandibular buboes usually develop secondary to the pharyngeal involvement. Cases arise following respiratory droplet exposure, or from the ingestion of undercooked meat.<sup>3,32</sup> Pharyngeal plague may give rise to secondary plague pneumonia. Care providers working in plague-endemic areas should be alert to the possibility of plague in the differential diagnosis of acute bacterial pharyngitis. Pharyngeal colonization with *Y. pestis* sometimes occurs without symptoms among contacts of persons with pneumonic plague. Epidemiological observations do not suggest that persons with pharyngeal carriage present a contagious threat to others.

## PATHOGENESIS AND IMMUNITY

### Molecular Basis of Disease

*Y. pestis* is one of the most virulent bacteria known; both chromosomal- and plasmid-encoded gene products are involved (see *Y. pestis* Virulence). A lipopolysaccharide endotoxin is thought to be primarily responsible for the pathogenic effects of plague sepsis, including SIRS, ARDS, excessive cytokine activation, complement cascade with resultant DIC and bleeding, unresponsive shock, and organ failure.<sup>37-40,44</sup>

Before antibiotics became available, nearly all persons with septicemic or pneumonic plague died rapidly from toxemia and organ failure.

### Tissue Invasion and Pathology

*Y. pestis* organisms inoculated through the skin or mucous membranes are carried via lymphatics to regional lymph nodes, although it is possible that direct bloodstream dissemination may occur. In the early stages of infection, affected lymph nodes are edematous, congested, and have minimal inflammatory infiltrates and vascular injury. Fully developed buboes, however, contain large numbers of infectious plague organisms and show hemorrhagic necrosis and a mild neutrophilic infiltration.<sup>44</sup> The affected nodes are usually surrounded by a serosanguineous effusion. When several adjacent lymph nodes are involved, a boggy, edematous mass can result. Spontaneous bubo rupture and suppurative drainage may occur.

Primary septicemia results when multiplication of *Y. pestis* occurs in the bloodstream in the absence of a bubo; secondary septicemic plague develops when primary lymphadenitic or pulmonary disease occurs, local defenses are breached, and infections spill over into the bloodstream. Newly inoculated plague bacilli are able to survive phagocytosis and be disseminated by mononuclear cells to distant sites. *Y. pestis* can invade and cause disease in almost any organ, and untreated infection usually results in widespread and massive tissue destruction. A diffuse interstitial myocarditis with cardiac dilation, multifocal necrosis of the liver, diffuse hemorrhagic splenic necrosis, and fibrin thrombi in renal glomeruli are common findings at autopsy.<sup>44,45</sup> If DIC occurs, the result is thrombosis and vascular necrosis with widespread cutaneous, mucosal, and serosal petechiae and ecchymoses.<sup>37,38,45</sup>

Pneumonic plague can result from inhalation of infective respiratory droplets from a person or animal with respiratory plague or secondary to hematogenous spread in a patient with bubonic or septicemic plague. It can result also from inhalation of *Y. pestis* in a laboratory accident.<sup>46</sup> Primary plague pneumonia generally begins as a lobular process and then extends by confluence, becoming lobar and then multilobar. Typically, plague organisms are most numerous in the alveoli. Secondary plague pneumonia begins more diffusely as an interstitial process, with organisms initially most numerous in the interstitial spaces. In untreated cases of both primary and secondary plague pneumonia, the usual findings are diffuse pulmonary hemorrhage, necrosis, and scant neutrophilic leukocyte infiltration.<sup>42</sup>

### Immunity

*Yersinia pestis* resists the innate host defense mechanisms such as phagocytosis and the induction of inflammatory responses by macrophages and neutrophils. On contact with eukaryotic cells, yersiniae release LcrV into the medium and deliver six effector Yops directly into the eukaryotic cell cytoplasm through a type III secretion system.<sup>47</sup>

Yersiniae have multiple mechanisms for suppression of the mammalian innate immune response. LcrV signals in a CD14- and toll-like receptor 2 (TLR2)-dependent fashion leading to immunosuppression by interleukin (IL)-10 induction.<sup>48,49</sup> LcrV together with YopB inhibit expression of phospho-p38, -p42/44, -JNK mitogen-activated protein kinases (MAPKs) and

transcription factors nuclear factor (NF)- $\kappa$ B, *c-fos*, and *c-jun* in lipopolysaccharide (LPS)-treated macrophages.<sup>50</sup> The inhibition in the expression of these signaling molecules correlates with the inhibition of TNF- $\alpha$  and nitric oxide production in macrophages.<sup>50</sup> YopJ causes downregulation of NF- $\kappa$ B and mitogen-activated protein kinase pathways and also causes downregulated production of proinflammatory cytokines, including TNF- $\alpha$ . The plague virulence protein YopM targets the innate immune response by causing a global depletion of natural killer (NK) cells, possibly by blocking expression of functional IL-15R on NK cells and inhibiting IL-15 expression by macrophages. IL-15 is crucial for the maintenance and activation of circulating NK cells as well as for their development in the bone marrow.<sup>51</sup> YopM, after delivery to host cells through a type III secretion mechanism, is transported to the nucleus.<sup>51</sup> Production of IFN- $\gamma$  by NK cells is necessary for early activation of macrophages to mediate robust bactericidal activity, production of pro-inflammatory cytokines, and strong expression of Th1 cytokines. The depletion of NK cells during *Y. pestis* infection results in an early decrease in production of Th1 cytokines such as IL-12 and IL-18, and TNF- $\alpha$ . The loss of IFN- $\gamma$  expression in the *Y. pestis*-infected host may contribute to the absence of granulomas. In addition, decreased IFN- $\gamma$ -mediated macrophage activation in *Y. pestis* infection favors greater bacterial growth.

### DIAGNOSIS

Except in epidemic situations, a high index of clinical suspicion and a careful clinical and epidemiologic history and physical examination are required to make a timely diagnosis of plague. A delayed or missed diagnosis of plague is associated with a high case-fatality rate, and infected travelers who seek medical care after they have left endemic areas (peripatetic plague cases) are especially at risk.<sup>52,53</sup> When plague is suspected, close communication between clinicians and the diagnostic laboratory, and between the diagnostic laboratory and a qualified reference laboratory is essential. Laboratory tests for plague are highly reliable when conducted by persons experienced in working with *Y. pestis*, but such expertise is usually limited to specialized reference laboratories. Because of recent concerns with possible bioterrorism, a network of participating laboratories across the United States has been developed with the ability to make rapid and confirmatory diagnoses. All state public health laboratories now have this capability and can, if necessary, forward materials to the CDC for rapid advanced procedures.<sup>54</sup>

### Specimen Collection and Processing

When plague is suspected, specimens should be obtained promptly for microbiologic studies, chest radiographs taken, and specific antimicrobial therapy initiated pending confirmation. Appropriate diagnostic specimens for smears and culture include blood in all patients, lymph node aspirates in those with suspected buboes, sputum samples or tracheobronchial aspirates in those with suspected pneumonic plague, and cerebrospinal fluid in those with meningeal signs. A portion of each specimen should be inoculated onto suitable media (e.g., brain-heart infusion broth, sheep blood agar, chocolate agar, or MacConkey agar). Smears of each specimen

should be stained with Wayson or Giemsa stain, and with Gram stain, and examined using light microscopy. If possible, the specimens should also be examined using direct fluorescent antibody (FA) testing.<sup>14</sup> An acute phase serum specimen should be collected for *Y. pestis* antibody testing, followed by a convalescent phase specimen collected 3 to 4 weeks later. For diagnosis in fatal cases, autopsy tissues should be collected for culture, FA testing, and histological processing, including buboes, samples of solid organs (especially liver, spleen, and lung), and bone marrow. For culture, specimens should be sent to the laboratory either fresh or frozen on dry ice and not in preservatives or fixatives. Cary-Blair or a similar holding medium can be used to transport *Y. pestis*-infected tissues.

### Laboratory Confirmation

Laboratory confirmation of plague depends on the isolation of *Y. pestis* from body fluids or tissues. When the patient's condition allows, several blood cultures taken over a 45-minute period prior to treatment will often result in successful isolation of the bacterium. *Y. pestis* strains are readily distinguished from other gram-negative bacteria by polychromatic and immunofluorescence staining properties, characteristics of growth on microbiologic media, biochemical profiles, and confirmatory lysis by the *Y. pestis*-specific bacteriophage.<sup>14</sup> Laboratory mice and hamsters are susceptible to *Y. pestis* and are used in specialized laboratories to make isolations from contaminated materials and for virulence testing.

In the absence of cultural isolation of *Y. pestis*, plague cases can be confirmed by demonstrating a fourfold or greater change in serum antibodies to *Y. pestis* F1 antigen by passive hemagglutination (PHA) testing or by detecting a serum antibody titer of 128 or greater in a single serum sample from a patient with a compatible illness who has not received plague vaccine. The specificity of a positive PHA test is confirmed by F1 antigen hemagglutination inhibition (HI) testing. A small percentage of plague patients will develop diagnostic levels of antibodies within 5 days after the onset of illness, most seroconvert 1 to 2 weeks after onset, fewer seroconvert more than 3 weeks after onset, and less than 5% fail to seroconvert.<sup>55</sup> Early specific antibiotic treatment may delay seroconversion by several weeks. Following conversion, serologic titers diminish gradually over months to years. Enzyme-linked immunosorbent assays (ELISAs) for detecting immunoglobulin M (IgM) and IgG antibodies to *Y. pestis* are useful in identifying antibodies in early infection and in differentiating them from antibodies developed in response to previous vaccination. Recently, antigen capture ELISA procedures, polymerase chain reaction assays, and handheld immunodiagnostic antigen detection tests for rapid, early diagnosis have been developed and are being evaluated. The handheld devices allow diagnostic testing of clinical materials at the bedside, even under primitive conditions.<sup>56</sup>

### TREATMENT AND PROGNOSIS

Untreated, plague is fatal in over 50% of bubonic cases and in nearly all cases of septicemic or pneumonic plague. The overall plague case-fatality ratio in the United States in the past 50 years has been approximately 15%.<sup>57</sup> Fatalities are almost always due to delays in seeking treatment, misdiagnosis,

and delayed or incorrect treatment. Rapid diagnosis and appropriate antimicrobial therapy are essential. The case-fatality ratio is very high for pneumonic plague patients who begin treatment more than 18 to 24 hours after the onset of pulmonary symptoms.

Streptomycin has long been the treatment of choice for plague; this aminoglycoside is, however, no longer manufactured in the United States, is not widely available, and can cause irreversible ototoxicity in some patients. Because of its ready availability and ease of administration, gentamicin is replacing streptomycin as treatment for plague patients in the United States. Although comparative trials of safety and efficacy of streptomycin versus gentamicin in plague have not been conducted, case reports and a retrospective review of patients treated in New Mexico indicate that gentamicin is an acceptable substitute in the treatment of plague.<sup>58</sup> Tetracycline and chloramphenicol are effective alternatives to the aminoglycosides. Doxycycline has become the tetracycline of choice because of its ease of administration, rapid and efficient absorption after ingestion, and its superior ability to achieve and maintain peak serum concentrations following oral administration. Chloramphenicol is indicated for conditions in which high tissue penetration is important, such as plague meningitis, pleuritis, endophthalmitis, and myocarditis. Chloramphenicol can be used separately or in combination with an aminoglycoside. Treatment with doxycycline, tetracycline, or chloramphenicol should begin with loading doses.

Ciprofloxacin, a fluoroquinolone, has shown promise in vitro and in laboratory animal studies,<sup>59,60</sup> but case series demonstrating its utility in human plague have not been reported. Penicillins, cephalosporins, and macrolides have poor efficacy and should not be used. Trimethoprim-sulfamethoxazole has been used successfully to treat bubonic plague, but is not considered a first-line choice and is not recommended for treating severe forms of the disease. In general, antimicrobial treatment should be continued for 7 to 10 days or for at least 3 days after the patient has become afebrile and has made a clinical recovery. Patients begun on intravenous antibiotics may be switched to oral regimens as indicated by clinical response. Improvement is usually evident 2 to 3 days from the start of treatment, even though lessening fever may continue for several more days.

Guidelines for medical and public health management of a potential *Y. pestis* terrorist attack have been developed that recommend streptomycin or gentamicin as the first-line treatment for pneumonic plague in a contained casualty situation, substituted if necessary by oral doxycycline or ciprofloxacin in the event of mass casualties.<sup>2</sup>

Consequences of delayed treatment of plague include DIC, ARDS, and other complications of bacterial sepsis and endotoxemia. Patients with these disorders require intensive monitoring and close physiologic support. Buboes may require surgical drainage if they threaten to rupture. Abscessed nodes rarely can be a cause of recurrent fever in patients who have otherwise had satisfactory recovery; the cause may be occult when intrathoracic or intra-abdominal nodes are involved. Viable *Y. pestis* organisms have occasionally been isolated from buboes 1 to 2 weeks into convalescence. *Y. pestis* strains resistant to one or more antibiotics used to treat plague have rarely been isolated from humans but have not been associated with treatment failures. Recently, however, an isolate of

*Y. pestis* from a bubonic plague patient in Madagascar was found to have plasmid-mediated, transferable, high level in vitro antimicrobial resistance to all agents recommended as first-line agents in treating plague.<sup>61</sup> The patient recovered after treatment with streptomycin and trimethoprim-sulfamethoxazole, and no similar strains have been further identified from humans or from natural sources.

## PREVENTION AND CONTROL

### General Principles

Surveillance, environmental management, and personal protective measures are the cornerstones of prevention and control.<sup>9,62,63</sup> Surveillance includes environmental monitoring to determine sites of plague activity, inspection of rodent habitat for signs of epizootics, collecting and testing of fleas from abandoned burrows, trapping and testing of live rodents and their fleas for *Y. pestis* infection, and testing of animals found sick or dead from suspected plague. In some circumstances, carnivore seropositivity is used as an indicator of rodent plague activity in an area. Dogs and wild canines readily seroconvert following exposure but retain elevated antibody levels for less than a year, making them useful sentinels of recent plague activity in an area.

Personal protective measures include avoidance of areas with known epizootic plague (these may be posted by government authorities); avoidance of sick or dead animals; use of repellents, insecticides, and protective clothing when there is a potential for exposure to rodent fleas; and use of gloves when handling animal carcasses.

Postexposure treatment for 7 days with doxycycline or other tetracycline, chloramphenicol, or ciprofloxacin is recommended for persons who have had a known close exposure to a pneumonic plague patient in the prior 7 days. Oral doxycycline or ciprofloxacin has been recommended for postexposure prophylaxis in the event of a terrorist attack with *Y. pestis*.<sup>2</sup> Pre-exposure prophylaxis may occasionally be recommended for persons who are unable to avoid visiting or residing in an area where a plague outbreak is in progress or who are screening or caring for plague patients in unusual circumstances, such as an outbreak. To reduce the risk of airborne droplet spread, plague patients should have a chest radiograph to rule out pulmonary involvement. Patients with suspected pneumonic plague should be managed in isolation under respiratory droplet precautions until the patient has responded clinically and sputum cultures are negative (sputum typically is sterile within 24 to 48 hours of beginning treatment). Persons caring for sick animals (especially cats) in plague-endemic areas should take precautions to avoid contamination with infectious exudates or expelled respiratory secretions.<sup>30</sup>

Sources of rodent food (garbage, feed for livestock and pets) and shelter (brushpiles, junk heaps, woodpiles) should be eliminated in domestic, peridomestic, and working environments, and buildings and food stores should be rodent-proofed. Controlling fleas with insecticides is a principal public health measure in situations where epizootic plague activity places humans at high risk. This includes insecticidal dusting and spraying of rodent burrows, rodent runs, and other sites where rodents and their fleas are found. In known plague foci, pet owners should keep their dogs and cats free of fleas and restrained. The decision to control plague by

killing rodents should be left to public health authorities and should only be carried out in conjunction with effective flea control. Killing rodents has no lasting benefit without environmental sanitation.

In the event of a plague epidemic, measures should rapidly be taken to control spread, as described in international regulations and guidelines for plague control.<sup>9,11,62,63</sup> These measures include delineation of infected areas, rapid detection and treatment of cases and exposed contacts, isolation and monitoring of suspected human plague cases and case contacts, and control of fleas and rodents in plague-infected areas, in port facilities, and on ships and other conveyances as indicated. A rapid surveillance system to identify and contain the possible introduction of pneumonic plague into the United States was established at the time of the reported outbreaks of plague in India in 1994.<sup>64</sup>

### Plague Vaccine

No plague vaccine is currently available in the United States. Much research is under way to develop safe, rapidly acting, and efficacious vaccines using advanced molecular approaches.<sup>65</sup> The most promising of these is a vaccine that combines recombinant F1 and V antigens of *Y. pestis*, and early testing in humans is under way. Another approach in early stages of research is passive immunization with monoclonal antibodies against targeted *Y. pestis* antigens.

## Tetanus

BARNETT R. NATHAN  
THOMAS P. BLECK

### INTRODUCTION

Tetanus remains a significant health concern throughout the world. In 1975 Edsal estimated that about 1 million cases of the disease occurred annually in the world.<sup>1</sup> In the United States and other developed countries the number of cases and deaths from tetanus has fallen significantly over the last 40 years.<sup>2,3</sup> However, in the tropics and particularly the developing countries in these regions, tetanus, particularly neonatal tetanus, continues to be a significant cause of morbidity and mortality, with neonatal tetanus having an up to 90% mortality rate.<sup>4,5</sup> Technological advances such as pharmacologic muscle relaxants and ventilatory support have made the treatment of acute tetanus possible. Unfortunately, many of these techniques are not readily available in the developing world. Fortunately, an effective vaccine is available, and immunization programs are clearly effective in reducing mortality, particularly from neonatal tetanus.<sup>6</sup>

Tetanus was described very early in the history of medicine, with both the Egyptians and the Greeks recording the muscle rigidity and trismus that characterize the disease.<sup>7,8</sup> In the 18th century, tetanus was thought to be a result of nerve injury,<sup>9</sup> and the muscle spasms were also at times confused with the convulsions of epilepsy. In the 19th century, Sir William Gowers described quite accurately the typical appearance of a patient with tetanus: "Tetanus is a disease of the nervous system characterized by persistent tonic spasm, with violent brief exacerbations. The spasm almost always commences in the muscles of the neck and jaw, causing closure of the jaws (trismus, lockjaw), and involves muscles of the trunk more than those of the limbs. It is always acute in onset, and a very large proportion of those who are attacked die."<sup>10</sup> Nicolaier reported a strychnine-like toxin from anaerobic soil bacteria in 1884,<sup>11</sup> and 6 years later Behring and Kitasato demonstrated that immunization with an inactivated extract of this bacterium prevented tetanus.<sup>12</sup>

In the 18th century neonatal tetanus was known as the "7-day disease" in the Americas<sup>13</sup> and as the "9-day fits in Dublin"<sup>14</sup> because it usually presents about 1 to 2 weeks postpartum. In 1846, Sims conjectured that neonatal tetanus resulted from placing infants on their backs, thereby compressing the occiput and occluding the blood supply to the medulla.<sup>15</sup> In 1887, 3 years after Nicolaier's report, Beumer determined that the umbilicus was the portal of entry for neonatal tetanus.<sup>16</sup>

### AGENT

*Clostridium tetani* is a slender, obligate anaerobic bacillus measuring 0.5 to 1.7  $\mu\text{m}$   $\times$  2.1 to 18.1  $\mu\text{m}$ .<sup>17</sup> Although classified as a gram-positive organism, it may stain variably, especially in tissue or older cultures.<sup>18</sup> Most strains are slightly motile, and have abundant peritrichous flagella during growth.<sup>19</sup> The mature organism loses its flagella and forms a spherical terminal spore,<sup>20</sup> producing a profile like that of a squash racket (Fig. 43-1).<sup>21</sup> The spores resist extremes of temperature and moisture and they are stable at atmospheric oxygen tension. The spores can survive indefinitely and are viable after exposure to ethanol, phenol, or formalin. Death of the spores can be ensured by exposure to 100°C for 4 hours, autoclaving at 121°C and 103 kPa (15 psi) for 15 minutes, or with iodine, glutaraldehyde, or hydrogen peroxide.

Spores can be isolated from animal feces and therefore are ubiquitous in the environment. In small numbers they can be found in the soil and even on carpets, and hence any breach in skin defenses such as wounds, burns, animal bites, human bites,<sup>22</sup> and even insect bites may result in inoculation of the spores.<sup>23</sup> Close to 80% of tetanus cases in the United States between 1972 and 1989 were the result of acute injuries (with equal contributions from punctures and lacerations as the acute wound type likely to cause tetanus), while only 20% were the result of more chronic wounds.<sup>24</sup> There was only a slight preponderance of patients acquiring tetanus while indoors as compared with outdoors (29% vs. 21%).<sup>24</sup> In many series, however, between 7% and 21% of tetanus cases are cryptogenic.<sup>25</sup>

In culture, the bacterium grows best at 37°C and will grow on a variety of media (including blood agar) as long as oxygen is excluded. Standard anaerobic isolation techniques, such as placing the sample in an anaerobic transport system, are important in the culture of the organism. However, diagnostic and therapeutic decisions should not be made based on the culture, since cultures are frequently negative in patients with clinical tetanus, and routine bacteriologic studies do not

**FIGURE 43-1** Gram's stain of a culture of *Clostridium tetani*. (Original magnification  $\times 1000$ .) (From Bleck T, Brauner JS: Tetanus. In Scheld WM, Whitley RJ, Durack DT [eds]: Infections of the Central Nervous System, 2nd ed. New York, Raven Press, 1996; courtesy of P. C. Schreckenberger and A. Kuritzin.)

**FIGURE 43-2** Reported annual incidence of all tetanus cases (including neonatal) by tropical region for years 1990 to 1995. Values along the abscissa represent the total number of cases reported to WHO. \*No report from India in 1995. (Adapted from World Health Organization: Global programme on vaccines: Total tetanus incidence data. 1996. Available at: [gopher://gopher.who.ch:70/11/.whosis/gpvis/incidence/total-tetanus/](http://gopher://gopher.who.ch:70/11/.whosis/gpvis/incidence/total-tetanus/).)

indicate whether a strain of *C. tetani* carries the plasmid required for toxin production.

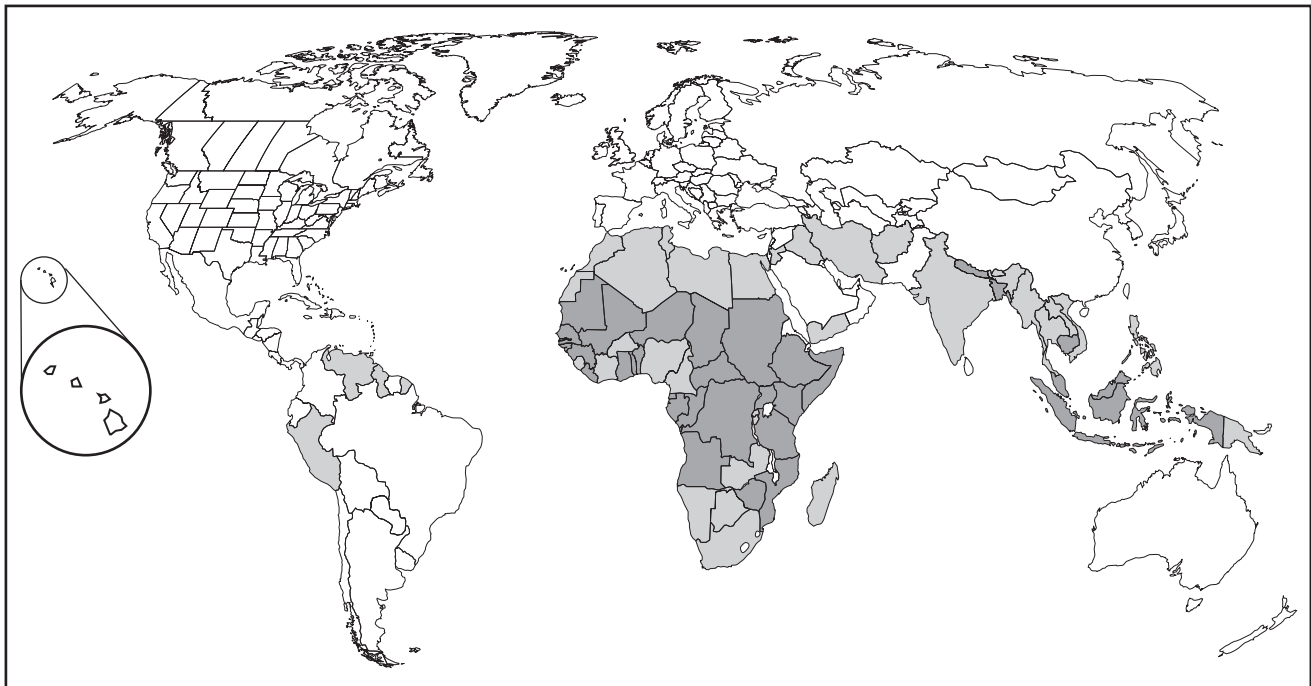

## EPIDEMIOLOGY

About 1 million cases of tetanus occur annually worldwide, suggesting an incidence of approximately 18 per 100,000 population per year,<sup>1</sup> but this number has a high degree of uncertainty because reported cases of tetanus are significantly lower

than this estimate. In tropical and developing countries tetanus continues to be a significant problem, with more than 45,000 cases reported in 1994. Figure 43-2 demonstrates the total number of reported tetanus cases throughout the tropical world. In the tropics and developing countries the number of neonatal cases has also dropped more than 50% while the total number of cases of tetanus has remained relatively stable. Figure 43-3 demonstrates the number of reported neonatal tetanus cases throughout the tropics. Neonatal tetanus

**FIGURE 43-3** Reported annual incidence of neonatal tetanus by tropical region for years 1990 to 1995. Values along the abscissa represent total number of cases reported to WHO. (Adapted from World Health Organization: Global programme on vaccines: Neonatal tetanus incidence data. 1996. Available at: [gopher.who.ch:70/11/.whosis/gpvis/incidence/neonatal-tetanus/](http://gopher.who.ch:70/11/.whosis/gpvis/incidence/neonatal-tetanus/).)

accounts for approximately half of the total number of cases worldwide and has up to a 90% mortality rate.<sup>4,5</sup> Eighty percent of worldwide neonatal tetanus cases occur in Bangladesh, China, Ethiopia, India, Indonesia, Kenya, Nepal, Nigeria, Pakistan, Somalia, Sudan, Uganda, Vietnam, and Zaire.<sup>26</sup> There is an estimated total of 120,000 deaths annually in the African region due to neonatal tetanus, which accounts for 10% to 30% of infant deaths in many countries.<sup>27</sup> In 1994 an estimated 500,000 deaths from neonatal tetanus occurred worldwide, but since the 1980s it is estimated that the number of deaths from neonatal tetanus has been cut in half through vaccination before or during pregnancy and with clean delivery and cord care practices.<sup>26</sup> Vaccinating the mother at this stage gives her long-term protection but, also importantly, protects the newborn during the first few weeks of life. Figure 43-4 demonstrates a decrease in the number of all tetanus cases, but particularly neonatal tetanus, since 1990. The World Health Organization has established the goal of eliminating maternal and neonatal tetanus by 2005,<sup>28</sup> but reality in the forms of war and inadequate resources has delayed this achievement.

## DISEASE

Tetanus is classified into four clinical subtypes: generalized, localized, cephalic, and neonatal. These four clinical subtypes represent the site of toxin action, either predominantly at the neuromuscular junction or at more central inhibitory systems. Incubation time (the time from spore inoculation to first symptoms) for all clinical types seems to vary depending on the ultimate severity of the disease, with more severe

disease developing more quickly ( $8.3 \pm 4.7$  days) and mild disease taking longer ( $11 \pm 6.7$  days).<sup>29</sup> The length of the incubation period also varies with the distance of the inoculation site from the central nervous system (CNS), so that injuries to the lower extremities have longer incubation periods than those occurring at more proximal sites.

Generalized tetanus is the most commonly recognized form of the disease. Trismus, or lockjaw, is the most common presenting sign. It is caused by rigidity of the masseter muscles, which in turn prevents the opening of the mouth, and its severity can be gauged by measuring the distance between the upper and lower teeth with the mouth maximally opened. Trismus results in the classic and characteristic risus sardonicus (Fig. 43-5), a facial expression which consists of lateral extension of the corners of the mouth, raised eyelids, and wrinkling of the forehead. These facial features may at times be subtle and may require comparisons with old photographs or confirmation of a change by the patient's family or friends.

Involvement of other muscle groups can then follow the onset of trismus: first the neck, then the thorax and abdomen, and finally the extremities. Tetanic spasms or generalized spasms resemble opisthotonus, decerebrate posturing, or even seizures, and are elicited by both external (noises, drafts of air, touching the patient) or internal (full bladder, coughing) stimuli. The tetanic spasms last for a few seconds to minutes and occur at irregular intervals. These spasms are extremely painful, and full consciousness is retained; this helps differentiate them from seizures or decerebrate posturing. Tetanospasmin is epileptogenic in experimental models, but true epileptic seizures in tetanus are rare. Respiratory compromise is the

**FIGURE 43-4** Total number of all tetanus cases and total neonatal tetanus cases reported worldwide from 1990 to 1994. The total number of cases is represented along the abscissa. Note the trend in the decreasing number of cases in this 5-year period, particularly in neonatal tetanus, likely due to increases in immunization worldwide. (Adapted from World Health Organization: Global programme on vaccines: Total tetanus incidence data. 1996. Available at: [gopher://gopher.who.ch:70/11/.whosis/.gpvis/.incidence/.total-tetanus](http://gopher://gopher.who.ch:70/11/.whosis/.gpvis/.incidence/.total-tetanus); and World Health Organization: Global programme on vaccines: Neonatal tetanus incidence data. 1996. Available at: [gopher://gopher.who.ch:70/11/.whosis/.gpvis/.incidence/.neonatal-tetanus](http://gopher://gopher.who.ch:70/11/.whosis/.gpvis/.incidence/.neonatal-tetanus).)

most serious early problem in generalized tetanus. Spasm of the glottis may occur and results in death via asphyxiation. The diaphragm and abdominal musculature are also frequently affected and this can result in apnea. This effect may be either central or directly at the neuromuscular junction (NMJ),<sup>30</sup> causing paralysis of these muscles. Deep tendon reflexes are usually hyperactive. After several days of illness, autonomic dysfunction, usually a hypersympathetic state, is noted in patients with severe tetanus. Autonomic dysfunction is now the leading cause of death in tetanus patients.<sup>31</sup> It is characterized by labile hypertension and tachycardia, arrhythmias, peripheral

vascular constriction, diaphoresis, pyrexia, increased carbon dioxide output, increased urinary catecholamine excretion, and sometimes hypotension. The disease may continue to progress for 10 to 14 days, reflecting the time it takes for the toxin to be transported to the CNS. Recovery then begins, usually taking about 4 weeks. Without antitoxin, the disease persists for as long as the toxin is produced. Because toxin is produced in insufficient quantities to stimulate an immune response, patients who survive tetanus have little in the way of natural immunity and recurrent tetanus is well documented.<sup>32,33</sup>

**FIGURE 43-5** The photograph on the left demonstrates risus sardonicus. Note the straightened upper lip at rest. The photograph on the right demonstrates trismus. The patient was instructed to open his mouth as fully as possible. (From Bleck T, Brauner JS: Tetanus. In Scheld WM, Whitley RJ, Durack DT [eds]: *Infections of the Central Nervous System*, 2nd ed. New York, Raven Press, 1996.)

Localized tetanus is characterized by fixed rigidity of the muscles at or near the site of injury. This may be mild, may persist for months, and usually resolves spontaneously. The muscle may be painful, and deep tendon reflexes may be brisk. The toxin may affect the NMJ, causing weakness, as well as rigidity. Partial immunity to the toxin may be responsible for preventing further hematogenous spread and generalized tetanus,<sup>34</sup> but unless treated, localized tetanus frequently evolves to the generalized form.

Cephalic tetanus occurs with injuries to the head or at times is associated with *C. tetani* infections of the middle ear.<sup>35</sup> Patients have weakness of the facial musculature, and facial paresis is common.<sup>36</sup> Dysphagia<sup>37</sup> and extraocular muscle<sup>38</sup> involvement also have been reported. The incubation period is usually 1 to 2 days. This is an unusual form of tetanus, and it too can evolve to the generalized form if left untreated.

Neonatal tetanus is a generalized form of the disease and is far more common in developing countries than in the developed world. It is the leading cause of neonatal mortality in many parts of the world, and of the diseases that can be vaccinated against it is second only to measles as a cause of childhood death.<sup>39</sup> It usually follows an infection of the umbilical stump, often because of improper wound care. In addition, a lack of maternal immunity to tetanus, which, if present, would be passively transferred to the neonate, is necessary for the development of this disease. Four factors seem to play a role in developing neonatal tetanus: (1) the length of the stump (a shorter stump appears to increase the risk), (2) the care with which the cord is ligated, (3) the cleanliness of the instruments and dressings, and (4) the cleanliness of the environment.<sup>40</sup> The incubation period is from 1 to 10 days postpartum, and the mortality rate is up to 90%, with the largest numbers of deaths in the first week of the disease. The infants usually are weak, irritable, and unable to suck. Tetanic spasms occur later, and the opisthotonic posturing must be differentiated from neonatal seizures or other metabolic or congenital abnormalities that cause posturing in this age group. The hypersympathetic state described previously also is common and is frequently the cause of death. Developmental retardation is common in those who survive.<sup>41</sup>

## **PATHOGENESIS AND IMMUNITY**

The spores of *C. tetani* germinate and the bacteria proliferate when the redox potential of the tissue is low. Once the bacteria are growing, two exotoxins are produced: tetanospasmin and tetanolysin. The clinical significance of tetanolysin is unclear. It may aid in the damage of viable tissue near the wound site, lowering the redox potential and allowing for continued growth of anaerobes, perhaps by disrupting membrane channels.<sup>42,43</sup> There also is evidence that tetanolysin can cause electrocardiographic abnormalities and disseminated intravascular coagulation when given systemically in experimental animals.<sup>44</sup>

Tetanospasmin, or "tetanus toxin," is believed to cause all the typical clinical manifestations of tetanus. It is synthesized as a single 151-kD (1315-amino acid) chain.<sup>45–46</sup> This molecule is then cleaved by a bacterial protease into a heavy chain and a light chain, connected by a disulfide bridge.<sup>47</sup> The disulfide bridge is necessary for the activity of the toxin.<sup>48</sup> The more commonly accepted fragments are those derived from papain treatment, which cleaves the heavy chain at lysine 865, about

50 kD from the C-terminal end.<sup>49</sup> This is termed the *C fragment*, whereas the light chain and the N-terminal end, still linked by the disulfide bridge, are variously called the *B fragment* or the *A-B fragment*. These chains are thought to affect different phases of toxin binding, cell entry, and toxicity. The DNA for this polypeptide resides on a single plasmid<sup>50</sup>; strains of *C. tetani* that do not have this plasmid have no toxigenic properties. Tetanospasmin inhibits neurotransmitter release at the presynaptic terminal,<sup>51</sup> and this accounts for the clinical presentation of tetanus. The toxin first binds to the presynaptic membrane and then must pass through it<sup>52</sup>; how this occurs is not entirely clear. Some studies suggest it does so through uncoated vesicles.<sup>53,54</sup> Other studies have demonstrated that it can produce pores in phospholipid and ganglioside vesicles,<sup>55</sup> suggesting perhaps another method of toxin entry. The toxin enters the cytoplasm via an acidic vacuole (similarly to diphtheria toxin). Other toxins, such as cholera, must enter via the Golgi apparatus before membrane translocation.<sup>56</sup> Once in the cytoplasm of the presynaptic terminal, tetanospasmin cleaves the protein (synaptobrevin) that "docks" the neurotransmitter-filled vesicle to the membrane, ultimately for fusion and then release.<sup>57</sup> Thus, because synaptobrevin is cleaved, the vesicle is unable to fuse with the membrane and the neurotransmitter cannot be released.

Tetanospasmin travels via retrograde transport back to the cell body and can then cross several orders of synaptically connected neurons. This process allows the toxin to move from the NMJ of alpha motor neurons to the spinal cord and ultimately to the brain, and helps explain its effects on the NMJ, autonomic function, and the CNS. The heavy chain of the toxin is necessary for the retrograde transport of the toxin to the cell body.<sup>58</sup> Tetanospasmin is also spread hematogenously but must still enter the CNS via neurons and retrograde transport. Any toxin that has not entered a neuron is potentially accessible to antitoxin antibody, but toxin that is intraneuronal or intra-axonal is not, and this helps explain the delay in improvement for several days after initiation of treatment.

Once transported to the spinal cord, tetanospasmin affects the inhibitory neurons. These neurons use either glycine or  $\gamma$ -aminobutyric acid (GABA) and normally inhibit the alpha motor neurons. Without this inhibition, the motor neuron increases its firing rate, ultimately causing rigidity of the muscle innervated by this neuron. More clinically relevant is the fact that without this inhibition, the normal relaxation of antagonist muscles is impaired, and the characteristic tetanic spasm occurs, in response to movement or stimulation. The toxin is transported into the brainstem,<sup>59</sup> but the clinical relevance of this is unclear.

Tetanospasmin disinhibits sympathetic reflexes at the spinal cord level, implying that hyperadrenergic findings do not depend on the hypothalamus or brain stem<sup>60</sup>; however, the development of the syndrome of inappropriate antidiuretic hormone (SIADH) secretion may support hypothalamic involvement.<sup>61</sup> Patients with tetanus occasionally develop bradycardia and hypotension,<sup>62</sup> as well as disruption of gastric motility,<sup>63</sup> indicating that parasympathetic function is also disrupted.

The effects of tetanospasmin at the NMJ have been established for more than 40 years.<sup>64</sup> More recent studies show a presynaptic defect in the release of acetylcholine (similar to botulism) demonstrated by single-fiber electromyography (EMG).<sup>65</sup>

NMJ recovery presumably depends on sprouting new synapses, but the original junctions eventually recover, after which the new ones are pruned. Although frequently overlooked, there may be significant weakness in tetanus, and the tetanospasmin effect on the NMJ is likely the reason.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of tetanus is primarily clinical. A clinical picture of trismus, muscle rigidity, stimulus-induced tetany, and a history of a wound or injury within the last 3 weeks is highly suggestive of generalized tetanus. Likewise, a newborn with a poor suck and increased muscle rigidity and spasms, in the setting of poor umbilical hygiene and a mother with no immunization history, likely has neonatal tetanus. EMG may demonstrate findings consistent with increased excitability of the motor neurons as well as NMJ blockade, although this is not specific for tetanus. *C. tetani* is rarely cultured from the wound, and in any case a positive culture does not prove the presence of the disease. Blood and serum studies are usually normal or non-specific, and cerebrospinal fluid (CSF) is usually normal. For the most part, laboratory studies help evaluate for other entities in the differential diagnosis.

Symptoms caused by strychnine, a direct antagonist at the glycine receptor, mimic tetanus. Abdominal muscle rigidity between spasms is more common in tetanus than strychnine toxicity, and trismus frequently occurs later with strychnine. A history of strychnine intoxication may be elicited, and the toxin may be found in the serum, urine, or gastric contents. Dystonic reactions to dopamine antagonists may be confused with tetanus; however, torticollis and oculogyric crisis can be seen in the former but never with tetanus. A brief trial of an anticholinergic agent, such as benztropine or diphenhydramine, which usually relieves dystonic reactions, can further differentiate dystonia from tetanus. Tetany produced by hypocalcemia or alkalosis is usually accompanied by Chvostek's sign (spasm of the facial muscles elicited by tapping on the facial nerve in the region of the parotid gland) and Trousseau's phenomenon (tapping the palm and eliciting palmar spasm). Tetany from these metabolic causes usually involves the extremities rather than the axial musculature, and trismus is much less common. Associated serologic studies confirm the diagnosis. Generalized seizures may be confused with tetanus, but the former, by definition, involves a loss of consciousness. Both, however, respond to benzodiazepines. Conversion reaction or "pseudotetanus" is a disorder in which the patient's movements resemble tetanus. Patients with psychiatric disease can at times be distracted, their movements or postures inconsistent, and there may be a history suggestive of secondary gain. Finally, while the nuchal rigidity of meningitis may resemble the neck stiffness of tetanus, the CSF in tetanus is invariably normal.

## TREATMENT

A patient with generalized tetanus or neonatal tetanus requires the facilities and the expertise of an intensive care unit (ICU) to survive. A review of 335 consecutive tetanus patients revealed that survival drastically improved after the development of ICUs (44% mortality vs. 15%) and that the major improvement came from prevention of death due to respiratory failure.<sup>66</sup> The mainstays of treatment include

(1) neutralizing existing toxin before it enters the nervous system, (2) inhibiting further production of tetanus toxin, (3) muscle relaxation and sedation, (4) management of autonomic instability, and (5) ventilatory, nutritional, and general ICU support. A time-based protocol that the authors have found effective in generalized tetanus is shown in Box 43-1.

Treatment of generalized tetanus should begin with administration of human tetanus immunoglobulin (HTIG). Blake and colleagues<sup>67</sup> demonstrated that a single dose of 500 IU is as effective as the standard dose of 3000 to 5000 IU. The smaller amount can be given as a single dose; this is important as each intramuscular (IM) injection is a potential stimulus for a tetanic spasm. Equine antitetanic serum may be more readily available, particularly in developing regions, but it has a much higher incidence of adverse reactions. It is dosed at 10,000 to 1 million units IM. Once the tetanus toxin has entered the motor neuron, it is no longer possible to neutralize it with the antibody. Intrathecal administration of HTIG is possible (although not approved by the U.S. Food and Drug Administration [FDA]) and some authors report that it may be advantageous<sup>68</sup>; however, other studies have failed to demonstrate a benefit.<sup>69</sup> Debriding the portal of entry does not change the course of the disease, although it may help prevent secondary infection. Antibiotic treatment should be initiated at the outset. In the only study comparing metronidazole and penicillin, the former was superior with significantly less progression of the disease, shorter hospitalization, and improved survival.<sup>70</sup> This may not represent a beneficial effect of metronidazole as much as a negative effect of penicillin, which is a GABA antagonist.<sup>71</sup> The dose of metronidazole is 500 mg intravenously (IV) every 6 hours for 7 to 10 days.

Muscle relaxation is best accomplished with benzodiazepines or baclofen. Diazepam, lorazepam, and midazolam are all effective. With all three agents, very large doses are required to control tetanic spasms; doses in excess of 500 mg/24 hr of diazepam, 200 mg/24 hr of lorazepam, and 0.1 to 0.3 mg/kg/hr of midazolam may be required. Intrathecal administration of baclofen also is effective.<sup>72,73</sup> If GABA receptor agonists, such as benzodiazepines or baclofen, are unsuccessful in controlling the muscle spasms, then neuromuscular blockade is necessary. Vecuronium (6 to 8 mg/hr) or pancuronium bromide as a bolus of 0.1 mg/kg, then infusion of 0.3 to 0.6 mg/kg/min, can be used. Vecuronium is preferred, since it is less likely to cause autonomic instability. A recent case report demonstrated the ineffectiveness of rocuronium in controlling tetany and spasms.<sup>74</sup> Of course, when paralytic agents are used, the patient must be intubated and ventilated with positive pressure. More likely, the patient will need to be intubated on presentation; this is done so as to protect the airway, which may occlude during tetanic spasms. Control of autonomic instability can be achieved with a variety of agents. Intravenous labetalol, a combined  $\alpha$ - and  $\beta$ -blocker, is the treatment of choice. Esmolol, clonidine, and morphine sulfate are also effective. Magnesium sulfate infusions can help with many aspects of the disease.<sup>75</sup> For bradycardia and hypotension, a temporary pacemaker may be necessary for the former, while fluid boluses and sympathomimetics (e.g., norepinephrine) may be required for the latter. The nutritional requirements of tetanus patients may be extraordinary, but once they are sedated and their spasms and autonomic activity suppressed, their nutritional requirements are similar to those of other critically

**Box 43-1** Management Protocol for Generalized Tetanus

- I. Diagnosis and stabilization: first hour after presentation
  - A. Assess airway and ventilation. If necessary, prepare for endotracheal intubation and neuromuscular junction blockade (e.g., vecuronium 0.1 mg/kg).
  - B. Obtain samples for antitoxin level, strychnine and dopamine antagonist assays, electrolytes, blood urea nitrogen, creatinine, creatine kinase, and urinary myoglobin determination. If meningitis is part of the patient's differential diagnosis, perform a lumbar puncture.
  - C. Determine the portal of entry, incubation period, period of onset, and immunization history.
  - D. Administer benzotropine 1 to 2 mg intravenously (IV) or diphenhydramine 50 mg IV to aid in excluding a dystonic reaction (see text for caveat).
  - E. Administer a benzodiazepine IV (diazepam in 5-mg increments, or lorazepam in 2-mg increments) to control spasms and decrease rigidity. Initially, employ a dose adequate to produce sedation and minimize reflex spasms. If this dose compromises the airway or ventilation, intubate using a short-acting neuromuscular blocking agent prior to transferring the patient to a quiet, darkened area of the intensive care unit.
- II. Early management phase: first 24 hours
  - A. Administer human tetanus immunoglobulin (HTIG), 500 units intramuscularly (IM).
  - B. At a different site, administer IM an absorbed tetanus toxoid such as tetanus-diphtheria vaccine 0.5 mL or diphtheria-tetanus-pertussis vaccine 0.5 mL, as appropriate for age. Adsorbed tetanus toxoid without diphtheria toxoid is available for patients with a history of reaction to diphtheria toxoid; otherwise, the correct combination for the patient's age should be employed.
  - C. If intrathecal administration of antitoxin is being considered, it should be administered at this point.
  - D. Begin metronidazole 500 mg IV every 6 hours for 7 to 10 days.
  - E. Perform a tracheostomy after placement of an endotracheal tube and under neuromuscular junction blockade if spasms produce any degree of airway compromise, or if dysphagia or difficulty managing secretions occurs.
  - F. Debride the wound if this is indicated for its own management (this has no apparent effect on the course of tetanus).
  - G. Place a soft, small-bore nasal feeding tube or a central venous hyperalimentation catheter.
  - H. Administer benzodiazepines as needed to control spasms and produce sedation. If adequate control is not achieved, institute long-term neuromuscular junction blockade (e.g., with a vecuronium infusion or intermittent pancuronium injections). Continue benzodiazepines for sedation with electroencephalographic monitoring to ensure somnolence.
  - I. Initiate physical therapy for pulmonary toilet and passive range-of-motion exercises as soon as the patient has been stabilized pharmacologically. Additional sedation should be given before each treatment, and again during the treatment if the therapy provokes spasms.
- III. Intermediate management phase: next 2 to 3 weeks
  - A. Treat sympathetic hyperactivity with IV labetalol 0.25 to 1.0 mg/min or morphine 0.5 to 1.0 mg/kg/hour. Consider epidural blockade with local anesthetics. Avoid diuretics for blood pressure control, because volume depletion will worsen autonomic instability.
  - B. If hypotension is present, place a pulmonary artery catheter and an arterial line, and administer fluids, dopamine, or norepinephrine.
  - C. Sustained bradycardia usually requires a pacemaker. Atropine or isoproterenol may be useful during pacemaker placement. External pacing should be avoided unless the patient is under neuromuscular junction blockade.
  - D. Begin prophylactic heparin to prevent pulmonary embolism.
  - E. Use a flotation bed, if possible, to prevent skin breakdown and peroneal nerve palsies. Otherwise, ensure frequent turning and employ antirotation boots.
  - F. Maintain benzodiazepines until neuromuscular junction blockade, if employed, is no longer necessary, and the severity of spasms has diminished substantially. Taper the dose over 14 to 21 days.
  - G. Begin rehabilitation planning.
- IV. Convalescent stage: 2 to 6 weeks
  - A. When spasms are no longer present, begin physical therapy. Many patients require supportive psychotherapy.
  - B. Before discharge, administer another dose of the appropriate tetanus toxoid combination.
  - C. Schedule a third dose of toxoid to be given 4 weeks after the second.

Adapted from Bleck T, Brauner JS: Tetanus. In Scheld WM, Whitley RJ, Durack DT (eds): *Infections of the Central Nervous System*, 2nd ed. New York, Raven Press, 1996.

ill patients. Gastric emptying may be impaired, and therefore, central venous nutrition may be necessary.

There is no standard regimen for the treatment of neonatal tetanus; however, it is treated much like generalized tetanus. Tetanus antitoxin should be administered to neutralize the tetanospasmin that has not yet entered neurons. Human anti-tetanic immunoglobulin is preferred with a single dose of 3000 to 5000 units IM, but as noted previously a smaller dose may also be effective (although not specifically tested in children). Equine antitoxin is more widely used because of its availability,

but serum sickness or allergic reactions are, of course, a significant concern. A single dose of 5000 units of equine antiserum is appropriate. A recent study in neonatal tetanus failed to show any advantage for intrathecal antitoxin.<sup>70</sup> Although debridement of the wound or infected umbilical stump may be surgically indicated, there is no evidence that debridement itself helps prevent progression of the disease. Eradication of the organism can be accomplished with penicillin 100,000 units/kg/day, although penicillin, being a GABA antagonist, can theoretically act synergistically with tetanospasmin and

worsen spasms. Metronidazole may be a better choice. Sedation and muscle relaxation of the neonate can be accomplished with a variety of agents including, for acute control of spasms, paraldehyde 0.3 mL/kg IM or diazepam 1 to 2 mg/kg IM or IV; and for chronic sedation, phenobarbital 5 mg/kg every 6 hours, or diazepam 1 to 2 mg/kg every 6 hours. Chronic ICU support must also be maintained as described previously for generalized tetanus.

## PREVENTION AND CONTROL

Active immunization with tetanus toxoid is one of the most effective preventive measures in medicine. Preventing one case of tetanus saves enough health-care expense to immunize several thousand people.<sup>76</sup> Active immunization with three IM injections of alum-adsorbed tetanus toxoid (10 lyophilized units, 0.5 mL) provides almost complete immunity for 5 years. Routine immunization in the infant begins at 6 weeks to 2 months of age with two other immunizations at 1- to 2-month intervals. A fourth vaccination should be given 1 year after the third, and a fifth at 4 to 6 years of age. Children under 7 years of age should receive the combined diphtheria-tetanus-pertussis (DTP) vaccine, while the tetanus-diphtheria (Td) vaccine is recommended for those older than seven. Several studies demonstrate that the pertussis component of the vaccine can be given in acellular rather than cellular form with fewer side effects and better efficacy in preventing pertussis.<sup>77</sup> This DTP vaccine has been approved by the FDA.<sup>78</sup> The complete series must be given to ensure adequate antibody titers. Routine boosters should be administered every 10 years.

In the developing world, neonatal tetanus remains a significant problem owing to large numbers of unimmunized women of childbearing age. Recently, a single dose of tetanus toxoid was administered to unimmunized pregnant women in their third trimester; both the mothers and their babies developed protective antibody titers.<sup>79</sup> Studies have also demonstrated that both human immunodeficiency virus-infected adults and

infants have the ability to develop protective tetanus antibody titers.<sup>80,81</sup>

Immunization after an injury that might cause tetanus (contaminated wound, puncture, burn, frostbite, avulsion, and crush injury) should be performed if no tetanus booster has been given within the last 5 years. An injured patient should be boosted with the adsorbed Td vaccine if none has been administered within the last 10 years. If a prior immunization history is unavailable, then a series of three monthly Td injections should be performed. HTIG should also be administered (250 to 500 IU) to a patient with no clear previous vaccination history, particularly if the wound is likely to cause tetanus. Most authors agree that both HTIG and tetanus toxoid can be given simultaneously, as long as different sites are used. Tables 43-1 and 43-2 represent the current recommendations of the American College of Emergency Physicians for immunization after injury in children less than 7 years of age and older children and adults.<sup>82</sup>

On the horizon are other methods of immunization. Sustained-release tetanus toxoid may be available in the future, allowing for a vaccination schedule with fewer doses.<sup>83</sup> Oral immunization has been demonstrated in mice by genetically engineering a mutant live *Salmonella typhi* strain to carry a fragment of the tetanospasmin gene (fragment C),<sup>84</sup> and oral or nasal administration of liposome-incorporated tetanus toxoid may be possible.<sup>85</sup>

## B. SPIROCHETAL INFECTIONS

# 44

## Treponemal Infections

EDWARD W. HOOK, III

### INTRODUCTION

Treponemal infections of humans have a worldwide distribution and include both venereal syphilis, caused by *Treponema pallidum* subsp. *pallidum* and the endemic treponematoses, which include yaws (*T. pallidum* subsp. *pertenue*), pinta (*Treponema carateum*), and endemic syphilis (*T. pallidum* subsp. *endemicum*). Although venereal syphilis is a worldwide problem associated with sexual transmission by persons with multiple sexual partners, endemic treponematoses are primarily childhood diseases that are most common in tropical regions and are usually spread from person to person by direct, non-sexual contact. Nonetheless, there are numerous important similarities in the causative agents, the natural history of infection, diagnostic tests, and therapy that translate into similar approaches to management. In this chapter, before discussing the individual diseases, we address the common microbiologic, clinical, and therapeutic elements of these infections.

### AGENTS

The pathogenic treponemes are thin, motile, organisms that are approximately 0.15  $\mu\text{m}$  in diameter and 6 to 50  $\mu\text{m}$  in length. The treponemes pathogenic for humans (*T. pallidum* subsp. *pallidum*, *pertenue*, and *endemicum* and *T. carateum*) are indistinguishable from one another microscopically and serologically.<sup>1,2</sup> Pathogenic treponemes cannot be cultivated for prolonged periods in vitro, although *T. pallidum* has been successfully cultivated for periods of days. Unlike the *T. pallidum* subspecies, which can also be propagated in small animals such as rabbits and hamsters, *T. carateum* can only be grown in primates. Despite these similarities, studies utilizing polymerase chain reaction amplification and restriction endonuclease cleavage of the genetic sequences flanking the region coding for a 15-kDa lipoprotein have been used for the first time to successfully and reliably differentiate *T. pallidum* subsp. *pallidum* from *T. pallidum* subsp. *pertenue* and *endemicum* (the authors were unable to evaluate *T. carateum* because, inasmuch

as it cannot be propagated in nonprimates, there are no examples of this organism in existing treponemal strain banks).<sup>3</sup> Using dark field microscopy for visualization, pathogenic treponemes typically have 6 to 14 regularly coiled spirals, and viable organisms move with a spinning, corkscrew motility, often flexing at the midpoint. The organism is tapered at either end and has an outer membrane that, unlike the typical protein-rich membranes of most bacteria, is largely made up of phospholipids with relatively few surface-exposed proteins.<sup>4,5</sup> Some investigators have suggested that the relatively protein-deficient surface structure of treponemes may be related to the tendency for these infections to progress despite their capacity to elicit high-titer, diagnostic antibody responses to what are most often non-surface-exposed internal antigens. Between the organisms' outer membrane and the cell wall are six axial fibrils (three at either end), which contribute to the typical motility of the organism.

### EPIDEMIOLOGY

Syphilis and the endemic treponematoses originate following inoculation of pathogenic organisms at mucosal or cutaneous surfaces. Infection is facilitated by breaks (microscopic or otherwise) in epithelial surfaces. Infectivity of treponemal infections may vary somewhat according to the histopathologic location of the organisms within lesions.<sup>6</sup> In yaws, the treponemes are predominantly present in the epidermis, unlike syphilis, in which organisms tend to be deeper and are found in the dermis or at the dermal-epidermal junction. Subsequent to inoculation and following an incubation period that not uncommonly may be a matter of weeks, the organisms cause primary cutaneous lesions at the site of inoculation. Primary lesions are most often solitary, but the lesion serves as a focus for subsequent spread of the organism, both locally through scratching and systemically via hematogenous routes to cause a more generalized rash and other lesions typical of the specific diseases. Following the early stages of clinical disease, which tend to be somewhat self-limited and resolve without treatment, infections enter latent stages. People with latent infections may experience periodic relapse for periods of as long as 5 years, at which time they are again infectious to others. During intervals when infected people are lesion-free, with the exception of congenital transmission of syphilis, they are not infectious to others. Untreated people with latent infections are also at risk of long-term sequelae of chronic infection. Unlike syphilis, central nervous system disease and perinatal transmission are believed to be rare, if not undescribed, in people with the endemic treponematoses. Because the treponemes are too thin to be readily visualized by light microscopy, diagnosis of infection may be made using dark-field microscopy of material from clinical lesions. Dark-field microscopy, however, is not readily available in the majority of settings where patients with syphilis or endemic treponematoses are encountered, and thus the diagnosis is often made on the basis of the clinical presentation or serologic diagnosis.

## DIAGNOSIS

The diagnosis of treponemal infections is most often accomplished using serologic tests. No serologic assays have been created specifically for the diagnosis of endemic treponematoses.<sup>1,2</sup> However, since no currently available commercial tests can serologically distinguish between antibody responses to syphilis and the endemic treponematoses, tests designed for syphilis<sup>7</sup> diagnosis have been and continue to be routinely utilized for diagnosis of yaws, pinta, and endemic syphilis. Two basic types of serologic tests are utilized to detect antibodies to the treponemes that cause syphilis and endemic treponematoses<sup>1,7,8</sup>: nontreponemal tests, which detect antibodies reactive with cardiolipin (diphosphatidylglycerol), which is also a normal component of many tissues, and, for evaluation of sera from patients found to be positive in nontreponemal tests, a “confirmatory” serologic test using specific treponemal antigens. The two-stage testing procedure is recommended in most instances because of the tendency for a small proportion (1% to 3%) of many populations to have false-positive nontreponemal serologic tests for syphilis.

The two most widely used nontreponemal tests are the VDRL (Venereal Disease Research Laboratory) test and the rapid plasma reagin (RPR) test.<sup>1,8</sup> Each test is based on flocculation reactions occurring when antibodies to treponemes react with a cardiolipincholesterol–lecithin antigen. Whereas the VDRL test can only use sera for testing and is slightly cheaper to perform, the RPR assay, which can be performed using either serum or plasma, is somewhat easier to perform and read. Both tests are usually performed using doubling dilutions of sera, allowing quantification of results, which can then be utilized to evaluate changes in antibody titers over time in response to therapy. People with treponemal infections typically develop serologic test reactivity within a few days after the appearance of primary infectious lesions at the site of inoculation.<sup>1</sup> Antibody titers then rise rapidly in the early stages of disease, falling either in response to therapy or more slowly after the manifestations of early infection resolve and the infection enters the latent stage. Following successful therapy, in many but not all patients, antibody titers will decline to low levels or even become nonreactive when tested using nontreponemal serologic tests.

False-positive serologic test results for syphilis (and other pathogenic treponemal infections) occur in 1 to 3% of most populations.<sup>1,8</sup> Biologic false-positive (BFP) test results may be transient or chronic, most often result in relatively low-titer serologic assay results (reactive in dilutions of 1:4 or less), and are identified by the fact that sera from patients with BFP nontreponemal test results rarely react in the treponemal serologic tests used to confirm the presence of pathogenic treponemal infection. Transient BFP results may occur in people with viral infections, following vaccinations, may be due to drug or other allergic reactions, or may occur in pregnancy. An increased prevalence of chronic BFP syphilis test reactivity is seen in people with chronic infections (endocarditis, leprosy, tuberculosis, human immunodeficiency virus [HIV] infection, etc.), with chronic inflammatory disorders (lupus erythematosus, rheumatoid arthritis, and antiphospholipid antibody syndrome), in parenteral drug users, and so on. Malarial infections are often cited as a cause of BFP syphilis tests in the tropics. BFP treponemal antibody test results may also be seen in people

who do not have any of the processes sometimes associated with increased test reactivity. BFP serologic tests for syphilis are usually reactive at low (1:4 dilution or less) titers, although a small proportion of people with BFP have higher titers. In many developing nations, where BFP may be common, endemic treponematoses are present, syphilis as well as other genital ulcer diseases (chancroid and genital herpes) are present, and it may be difficult to obtain treponemal test results, clinicians use titers above 1:8 to define “active syphilis” to guide therapeutic decision making. Although this approach probably has numerous exceptions, it is a useful generalization for resource-limited settings.

As mentioned previously, reactivity in treponemal serologic assays designed for syphilis diagnosis is utilized to distinguish people with treponemal infections from those with BFPs. Prototypal treponemal assays include the fluorescent treponemal antibody absorption (FTA-ABS) and microhemagglutination assay–*Treponema pallidum* (MHA-TP) assays, which, like all treponemal tests, are based on the reactivity of antitreponemal antibodies from people with syphilis or endemic treponematoses with prepared antigens from *T. pallidum*. In the FTA-ABS test, the antigens of rabbit-propagated *T. pallidum* are detected using indirect immunofluorescence microscopy, whereas in the MHA-TP, prepared *T. pallidum* antigens are bound to turkey red blood cells and used to detect antitreponemal antibodies in a hemagglutination assay. Although the MHA-TP test may be used quantitatively, in most instances treponemal serologic tests are used only as confirmatory tests to help distinguish people infected with one of the pathogenic treponemes from those with BFPs. Although less thoroughly studied than nontreponemal tests, false-positive assays do occur with treponemal tests as well. Thus, there is little benefit to the use of these more complex, more expensive tests for screening purposes. In addition, although in some patients with syphilis (and, by extension, the endemic treponematoses) treponemal test reactivity may return to a nonreactive state following therapy, in the majority of patients it does not. These tests are not routinely recommended to follow the response to therapy.

## TREATMENT AND PROGNOSIS

All treponemal infections appear to continue to be uniquely sensitive to relatively low doses of penicillin G.<sup>1,8,9</sup> The susceptibility of *T. pallidum* to the activity of long-acting benzathine penicillin, combined with the relatively long incubation period during which recently infected people are not infectious to others and the fact that these organisms only infect humans, makes pathogenic treponemal infections theoretically eradicable. For early infections, the recommended therapy usually consists of benzathine penicillin G, which provides low levels of penicillinemia for 2 or 3 weeks following a single injection. Using such therapy, cure rates for patients with early, active infections are 95% to 97%. In adults, the recommended therapy for syphilis is 2.4 million units of benzathine penicillin G given intramuscularly, whereas for endemic treponematoses 1.2 million units is recommended.<sup>7,9</sup> Although many other antimicrobial agents, including other penicillins, cephalosporins, tetracyclines, and macrolide antibiotics, are also active against *T. pallidum* subsp. *pallidum* (and probably other pathogenic treponemes as well), the low cost and efficacy of single-dose therapy have made benzathine

penicillin G the therapeutic agent of choice worldwide. Quinolone antibiotics, aminoglycosides, and sulfa drugs are not effective for treponemal infections. In some instances, it is possible that intercurrent therapy for other infections may also be beneficial for unappreciated treponemal infections, modifying the natural history of infection and reducing or eliminating infectivity.

Capitalizing on the ready availability of a diagnostic serologic test and the high efficacy of therapy using long-acting penicillins in the late 1940s and early 1950s, the World Health Organization outlined a strategy for eradication of endemic treponematoses using mass treatment with long-acting penicillin for large numbers of people or even entire populations.<sup>7,10,11</sup> In this plan, based on the results of serologic surveys that provided reliable estimates of the seroprevalence of infection, for populations with a prevalence of active yaws in excess of 10%, treatment of entire populations was recommended, whereas for populations with medium (5% to 10%) prevalence, treatment was to be administered to all children younger than 15 years of age and all contacts of infectious cases.<sup>7</sup> For populations with a lower (less than 5%) prevalence, rather than mass treatment, aggressive therapy of active cases and all household and other contacts was recommended. Other critical components of proposed programs for eradication of endemic treponematoses included careful follow-up to detect the anticipated small numbers of treatment failures, aggressive retreatment of those treatment failures and their contacts, and follow-up surveillance to prevent resurgence of disease. The yaws eradication campaigns resulted in a dramatic reduction in the prevalence of these infections. However, possibly as a

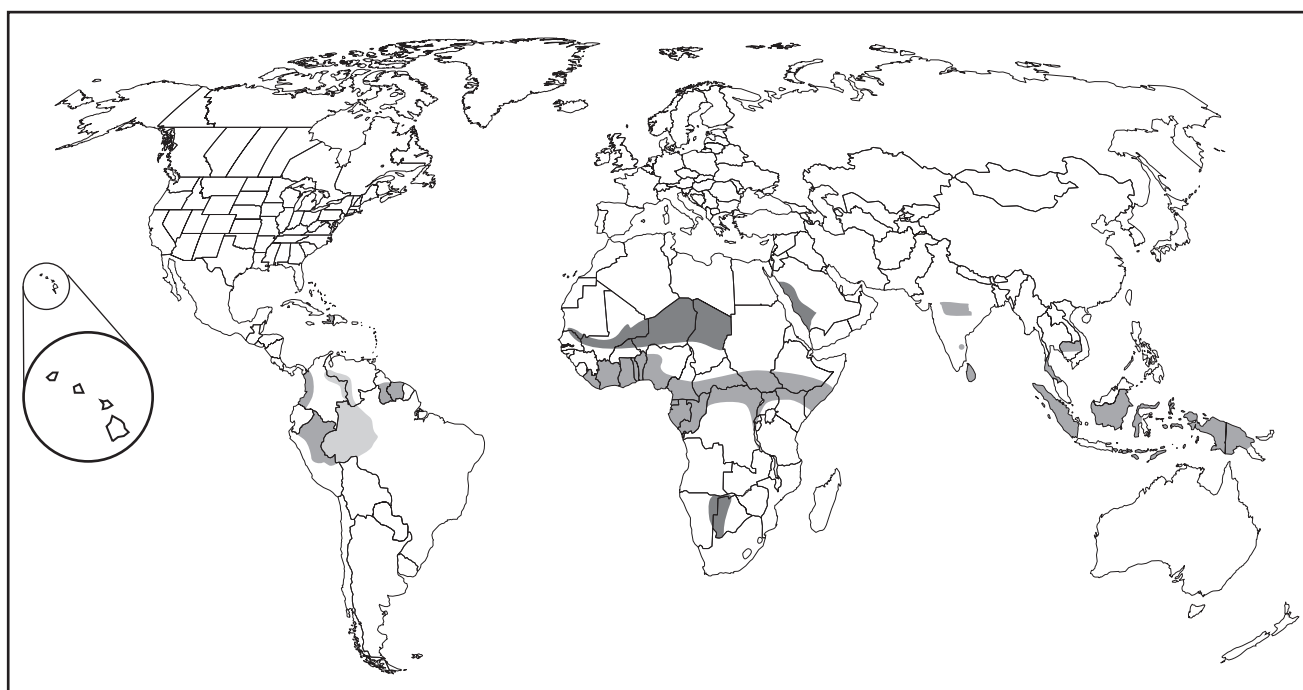

result of the failure of intensive follow-up and the persistence of small foci of infection, since the late 1980s yaws has again become more common in Africa, areas of the South Pacific, and Southeast Asia.

## CLINICAL PRESENTATION

The endemic treponematoses (and syphilis) cannot be distinguished from each other microbiologically or serologically. For people with early disease in endemic areas the clinical features and epidemiologic settings in which patients are encountered usually permit accurate presumptive diagnosis. In contrast, it may be quite difficult to accurately distinguish sporadically occurring treponemal infections from one another or to ascertain which infection has caused reactive treponemal serologic test results in a patient with latent or previously treated disease. The following sections describe the typical presentations and course of human treponemal infections.

### Yaws

Yaws is a disease of children (peak incidence at age 2 to 10 years) that is most common in warm, humid regions, including South and Central America, the Caribbean, equatorial Africa, and the equatorial islands of Southeast Asia.<sup>7,10,11</sup> The prevalence and incidence of yaws declined markedly during the yaws eradication campaigns of the 1950s, but in recent years the disease has again become more common. The infection is spread mainly by direct exposure to infectious lesions containing treponemes, possibly facilitated when compared with secondary

Endemic Treponematoses

- Pinta
- Yaws
- Endemic syphilis

syphilis by the epidermal location of organisms within cutaneous lesions.<sup>6</sup> The transmission of yaws is said to be enhanced by the presence of lesions (scrapes, abrasions, etc.), which may increase the infectiousness of inoculated treponemes, as well as social conditions that may increase the likelihood of direct contact between infected and uninfected people, such as crowding and deficiencies in community sanitation (e.g., lack of water for bathing and washing clothes).

The clinical manifestations of yaws vary over the course of the infection. An initial (primary) lesion appears at the site of inoculation after an incubation period of approximately 3 weeks (range, 9 to 90 days). The primary lesion is initially papular and typically enlarges to become a papilloma several centimeters in diameter (Fig. 44-1 and Plate 44-1). The primary papilloma (also referred to as a frambesioma or mother yaw) is a highly infectious lesion that may reveal numerous spirochetes upon examination of lesion exudate by dark-field microscopy and may persist untreated for as long as 3 to 6 months, after which time it resolves spontaneously. Prior to actual development of the primary papule, and while it is present in the primary stage, *T. pallidum* subsp. *pertenue* disseminates hematogenously, lymphatogenously, and through autoinoculation to give rise to secondary yaws. Local spread is facilitated by the pruritic nature of cutaneous lesions. Unlike syphilis, dissemination of *T. pallidum* subsp. *pertenue* is not known to cause neurologic disease or to be passed transplacentally to cause congenital infection.

The presentations of secondary yaws are quite varied and include a spectrum of cutaneous lesions as well as involvement of lymph nodes, bone (periostitis), and cartilage. Most cutaneous lesions are infectious to others and may appear anywhere on the body, presenting as macules, papules, nodules, or hyperkeratotic lesions, any of which may ulcerate. Unless suprainfection occurs, cutaneous lesions tend to heal (either spontaneously after periods of as long as 6 months or following therapy) without scarring. Interestingly, climate may influence the number and morphology of yaws lesions. Lesions tend to be fewer in number and are more likely to be macular during arid periods (or in arid regions) when papillomas are found mainly in moist parts of the body, such as the axillae, skin folds, and mucosal surfaces.

In patients with secondary yaws, nonsuppurative lymphadenitis presenting as swelling and tenderness of nodes draining cutaneous lesions is not uncommon. Periosteal and

**FIGURE 44-1** Initial, solitary yaws papilloma (frambesioma) on the upper thigh. (From Perine PL, Hopkins DR, Niemel PLA, et al: Handbook of Endemic Treponematoses: Yaws, Endemic Syphilis, and Pinta. Geneva, World Health Organization, 1984.)

**FIGURE 44-2** Bony deformity of the tibiae due to yaws osteoperiostitis. (From Perine PL, Hopkins DR, Niemol PLA, et al: Handbook of Endemic Treponematoses: Yaws, Endemic Syphilis, and Pinta. Geneva, World Health Organization, 1984.)

cartilaginous involvement may lead to pain, swelling, and local tenderness in patients with secondary yaws. Also characteristic of secondary yaws is the time course of untreated infection in which lesions resolve and then recur after a latent period when no lesions are present, most often in warm, moist body areas (the axillae, anus, and around the mouth). After 5 years, secondary recurrences are rarely seen, if at all. Over the natural history of untreated disease, the total duration of infectiousness to others is estimated to be 12 to 18 months.

Similar to syphilis, approximately 10% of patients with yaws may develop lesions of late infection that, although not infectious to others, may be disfiguring. Chronic periosteal involvement and resultant scarring may lead to disfiguring lesions, including the so-called saber shins, a bony deformity of the tibiae (Fig. 44-2). In addition, nodular lesions of late yaws may destroy cartilaginous structures such as the nose, an irreversible process known as gangosa.

### Endemic Syphilis

Like yaws, endemic syphilis, previously also referred to as *bejel* (Arabic), is a readily transmissible disease of children.<sup>7</sup> Although previously widespread among nomadic and semi-nomadic populations of North Africa, southwest Asia, and the eastern Mediterranean basin, endemic syphilis is now most common among nomads living in the Arabian peninsula and

along the southern border of the African Sahara desert. As might be inferred by its distribution, unlike yaws, which is more common in humid regions, endemic syphilis is more common in dry, arid regions.

Endemic syphilis is highly transmissible by contact with inanimate objects, such as shared drinking vessels, as well as by direct lesion contact contributing to spread.<sup>7</sup> Endemic syphilis is most common among children aged 2 to 15 years, who participate in the spread of infection to family members and others as well as provide a reservoir of infection.

Although often not clinically apparent, the primary lesions of endemic syphilis are nonetheless an important source of infection to others. The initial lesions, resulting from either direct or indirect inoculation, are painless mucous patches occurring on oral mucosal surfaces. The mucous patches of endemic syphilis are pale or white shallow ulcerations that may occur anywhere within the mouth. These lesions in turn may give rise to secondary lesions that may present as angular stomatitis (split papules) or more widely disseminated papular cutaneous lesions similar to those seen in yaws. Also similar to yaws, patients with endemic syphilis may experience a wide variety of secondary cutaneous lesions (papillomas, macules, and rashes of all types and locations) as well as periostitis, which may cause permanent bony deformity. Patients with late stages of endemic syphilis may also experience destruction of nasopharyngeal cartilage, causing gangosa.

## Pinta

Of all the human treponematoses, the least is known about pinta and its causative agent.<sup>7</sup> Pinta was only recognized as a treponemal disease in 1938 after demonstration of spirochetes in a lesion exudate from a patient with pinta. Unlike other *T. pallidum* subspecies, *T. pallidum* subsp. *carateum* causes infection only in man and higher primates and cannot be propagated in smaller, relatively inexpensive laboratory animals such as rabbits. As a result, there are no examples of the organism in treponemal strain banks for study.

The distribution of pinta is limited to the New World, having been described in semiarid regions of the Caribbean and South and Central America. Further distinguishing it from other endemic treponematoses, pinta is most common in young adults (peak incidence, age 15 to 30 years) and has a long duration of skin lesions and chronic cutaneous changes that result from untreated infection.

The primary lesion of pinta, most commonly occurring on exposed surfaces such as the legs, foot, forearm, or back of the hand, begins as a papule that gradually enlarges through local extension. These lesions may become hyperkeratotic and, over a period of 3 to 9 months, may change from a copper to a slate-blue color. Regional lymphadenopathy may be seen in patients with pinta. The later stage of pinta is also characterized by its cutaneous manifestations, which may be hyper- or hypopigmented. Unlike other treponematoses, the findings of late pinta are limited to the skin. Deep tissue or organ involvement has not been described.

## Syphilis

Syphilis and its causative agent, *T. pallidum* subsp. *pallidum*, are the best studied of all pathogenic human

treponemal diseases. The disease has been recognized by clinicians and medical scientists for approximately 500 years, and currently utilized diagnostic tests for human treponemal infections (dark-field microscopy and both treponemal and nontreponemal serologic testing) were developed to assist in the diagnosis and management of this disease and are applicable to diagnosis and management of endemic treponematoses on the basis of cross-reactivity with other *T. pallidum* subspecies. Similarly, most current treatments of nonsyphilitic treponemal infections are based on extrapolation of data from studies of syphilitic patients. Thus, despite the fact that syphilis is transmitted from sexual contact and follows a somewhat different natural history (particularly in its later stages), this infection provides the basis for most current understanding of all pathogenic treponemal infections in humans.

Syphilis has a worldwide distribution, but there is substantial regional variation in its prevalence.<sup>8</sup> Infection tends to be more common in developing countries, and among developed countries the prevalence of syphilis in the United States is 5 to 10 times higher than in any other nation. The infection is primarily transmitted through direct contact with infectious lesions, although parenteral transmission through needle sharing in the context of drug use and transmission through transfusion of unscreened whole blood account for a small number of cases.

The peak incidence of syphilis occurs among sexually active people aged 18 to 40 years, particularly in the context of having multiple sexual partners. Unlike the endemic treponematoses, syphilis may be transmitted to children born to infected mothers, giving rise to congenital infection as well.

The primary lesion of syphilis or the chancre typically occurs at sites of sexual exposure after an incubation period of approximately 3 weeks.<sup>8</sup> Although genital locations are most common, chancres are occasionally seen at other sites of inoculation, including the anus, cutaneous surfaces, and the oral cavity. A classic syphilitic chancre typically begins as a papule that quickly ulcerates to form a solitary, painless, clean-based ulcer approximately 8 to 15 mm in diameter. Untreated, such lesions may persist for 3 to 6 weeks prior to resolving without scarring. Soon after or at approximately the time when primary lesions resolve, the secondary manifestations of infection occur (primary lesions may persist in 10% to 15% of patients with secondary manifestations). Secondary lesions are highly varied in appearance and location. Cutaneous manifestations are most common. The so-called classic rash of secondary syphilis is composed of palmar or plantar, or palmar and plantar macular, lesions that may be 0.5 to 2.0 cm in diameter and are painless. The spectrum of cutaneous manifestations of secondary syphilis, however, is vast, giving rise to reference to this infection as the “great imitator.” Secondary syphilitic skin rashes may be generalized or focal; macular, papular, pustular, or a combination thereof; and resemble a wide variety of other cutaneous dermatoses. In addition to skin rashes, patients with secondary syphilis may develop highly infectious, heaped-up, papillomatous masses referred to as condylomata lata, mucous patches, and systemic lymphadenopathy. Although fever and other severe systemic manifestations are not common in patients with secondary syphilis, the disease is systemic and it is not unusual for patients to complain of generalized malaise. A small proportion of secondary syphilis patients may develop

glomerulonephritis or hepatitis. After approximately 6 months without treatment, the lesions of secondary syphilis resolve spontaneously and patients enter the so-called latent phase. Like yaws, however, for a period of approximately 5 years, secondary syphilitic manifestations may recur in patients with latent syphilis; the frequency of such recurrence decreases with the passage of time. After 5 years, clinical recurrences of syphilis occur rarely, if ever. Although the majority of patients with latent syphilis suffer no further sequelae, approximately one-third of untreated people will develop the late or tertiary stage of the infection. Based on natural history studies performed in Oslo, Norway, in the early 20th century, it appears that approximately 8% to 15% of untreated people develop cardiovascular syphilis, 15% develop gummatous syphilis, and 5% to 10% develop tertiary neurosyphilis.

Unlike the endemic treponematoses, *T. pallidum* subsp. *pallidum* regularly invades the central nervous system (CNS) and may cause neurologic disease. Even before the development of reactive serologic tests, *T. pallidum* subsp. *pallidum* was isolated from the cerebrospinal fluid (CSF) of patients with syphilis. Several studies, as well as work performed in the preantibiotic era, have repeatedly found *T. pallidum* in CSF of approximately 20% to 25% of patients with early (primary and secondary) syphilis and evidence of CNS involvement (elevated CSF lymphocyte concentrations, elevated CSF protein concentrations, or reactive CSF VDRL tests) in approximately half.<sup>12,13</sup> Although dissemination to the CNS occurs early in the course of infection, disease almost certainly does not occur in all patients with CNS invasion, and when it does, it tends to do so later in the course of the infection. The clinical manifestations of neurosyphilis, with substantial variation in severity and considerable temporal overlap, vary with the duration of infection. Early in the course of infection, most often during the secondary stage of disease, syphilitic meningitis occurs and rarely may be severe, but it usually resolves even if untreated. In contrast, neurosyphilis occurring later typically results in permanent neurologic damage. Four to 7 years after infection, medium-sized CNS arteriolar involvement may cause meningovascular neurosyphilis and stroke. The classic manifestations of progressive late (tertiary) neurosyphilis usually present even later, after 10 or more years of infection, as a severe, painful peripheral neuropathy (tabes dorsalis), dementia (general paresis), or a combination of the two. Progressive uveitis or iritis due to CNS syphilis may occur at any time after the secondary stage of infection.

In terms of management, despite evidence of frequent CNS invasion early in the course of infection, diagnostic lumbar puncture is recommended primarily for patients with neurologic findings, for evaluation of possible treatment failure, and for syphilis patients with coexistent HIV infection.<sup>9</sup> Studies have not demonstrated that lumbar puncture has substantial prognostic utility for guiding therapy.<sup>13</sup> For patients with proven neurosyphilis (known syphilis and abnormal CSF), high-dose penicillin therapy using either 18 to 24 million units of penicillin administered intravenously in divided doses for 10 to 14 days or 2.4 million units of aqueous procaine penicillin G administered intramuscularly plus 500 mg probenecid administered orally four times daily is recommended.<sup>9</sup> Many experts follow this high-dose therapy with administration of injections of 2.4 million units of

benzathine penicillin G given weekly for 3 weeks. Although asymptomatic CNS involvement may be present in patients with early or latent syphilis, these abnormalities usually resolve following treatment with currently recommended benzathine penicillin G therapy (Table 44-1), and thus lumbar puncture is not recommended for these patients.

Another way in which syphilis differs from other treponemal infections is the fact that *T. pallidum* may be passed transplacentally from infected mothers to their children. The prevalence of congenital syphilis leading to either miscarriage or clinical congenital syphilis decreases with increasing duration of disease. Thus, mothers who acquire infection during pregnancy are at highest risk of adverse outcomes, those with more recent acquisition of infection are at relatively high risk of adverse outcomes of pregnancy related to syphilitic infection, and the proportion of infected children born to these mothers diminishes with increasing duration of disease. Children with congenital syphilis may suffer lifelong disability, which includes cognitive impairment as well as bony and ocular changes.

Worldwide, syphilis has been epidemiologically linked to HIV infections (no similar associations have been described for endemic treponematoses). The shared mechanisms of transmission (sexual), the behavioral risks (multiple sexual partners), and the biologic amplification of both risk of acquisition and transmission of infection are thought to contribute to this association. Case reports earlier in the HIV epidemic suggested that the coexistence of syphilis and HIV may modify clinical and laboratory manifestations of infection. Recent larger studies, however,<sup>8,13</sup> suggest that although shifts in the spectrum of findings may occur in HIV-coinfected syphilis patients, these are differences in proportion and not previously undescribed manifestations of disease. Similarly, a randomized clinical trial of benzathine penicillin for treatment of early syphilis in patients with and without HIV<sup>13</sup> suggests that although there may be a slight increased risk of syphilis treatment failure among HIV-coinfected patients, the differences are not clinically significant. Thus, patients with early syphilis and HIV infection or acquired immunodeficiency syndrome (AIDS) should be treated using the same treatment regimens as used for people without HIV infection.<sup>13,14</sup> Many suggest, however, that repeat serologic testing to monitor response to therapy be performed over a longer period (2 years) than is typically suggested for follow-up of syphilis patients without coexistent HIV infection.

**Table 44-1 Recommended Treatment for Human Treponemal Infections**

Infection	Treatment
Endemic treponematoses (yaws, pinta, endemic syphilis)	
Age <10 yr	Benzathine penicillin 600,000 units IM
Age ≥10 yr	Benzathine penicillin 1.2 million units IM
Syphilis	
Early (primary, secondary, early latent)	Benzathine penicillin 2.4 million units IM
Late latent or latent syphilis of unknown duration	Benzathine penicillin 2.4 million units IM × 3

## Relapsing Fever and Other Borrelia Diseases

ALAN G. BARBOUR

### INTRODUCTION

Physicians have recognized relapsing fever as a distinct clinical entity since the time of Hippocrates.<sup>1</sup> There are few if any other diseases that are characterized by two or more episodes of high fever separated by weeklong periods of well-being. This unique clinical feature of relapsing fever allows retrospective recognition of the disease as sporadic cases and outbreaks in Europe, Asia, and North America during the past several centuries. The etiologic agent was one of the first to be identified during microbiology's dawn in the 19th century. Pioneer immunologists, such as Paul Ehrlich, were also interested in the disorder because it offered insights into the specificity and dynamics of the adaptive immune response.

Relapsing fever is an arthropod-borne zoonosis and occurs in two major forms: louse-borne and tick-borne (Table 45-1).

The tick-borne relapsing fever species are transmitted by soft (argasid) ticks. Both forms of relapsing fever have had global distributions. Isolated cases and epidemics have occurred in equatorial regions, temperate zones, and the subarctic in all hemispheres. Louse-borne relapsing fever has had, like plague and typhus, periods of huge impact on human health.

Lyme borreliosis (Lyme disease) is another common tick-borne zoonosis caused by *Borrelia* spp., but it is transmitted by hard (ixodid) rather than argasid ticks.<sup>2</sup> Whereas relapsing fever in one form or another exists on most continents, Lyme borreliosis has been documented only in the Nearctic (North America) and the Palearctic (Europe and temperate Asia) ecological regions. A diagnosis of autochthonous Lyme borreliosis in a resident of a tropical region is probably inaccurate.

Recently, another group of *Borrelia* spp. has been identified.<sup>3,4</sup> These are phylogenetically related to the relapsing fever species but use ixodid ticks as vectors rather than argasid ticks. One of these species, *Borrelia lonestari*, has been associated with human disease,<sup>5</sup> but the public health significance of this and other newly discovered species has yet to be determined.

### AGENTS

The agents of relapsing fever and Lyme borreliosis are spirochetes, which comprise a deep taxonomic division among eubacteria.<sup>6</sup> Spirochetes are spiral or wavy filamentous bacteria with the following characteristics: (1) two cell membranes, inner and outer, with a periplasmic space between; and (2) one to several flagella that are inserted at each end but not in the middle and traverse the length of the cell in the periplasmic space.<sup>7</sup>

Relapsing fever and Lyme borreliosis pathogens are in the genus *Borrelia*, which are host-associated microorganisms and

**Table 45-1** Comparison of Tick-Borne Relapsing Fever (RF), Louse-Borne RF, and Lyme Borreliosis

Characteristic	Tick-Borne RF	Louse-Borne RF	Lyme Borreliosis
Agent	Several species	<i>Borrelia recurrentis</i>	<i>Borrelia burgdorferi</i> sensu lato*
Vector	<i>Ornithodoros</i> spp. (soft ticks)	<i>Pediculus humanus corporis</i> (human body louse)	<i>Ixodes</i> spp. (hard ticks)
Usual reservoir	Rodents <sup>†</sup>	Humans	Rodents
Epidemiology	Endemic	Epidemic	Endemic
Distribution	Tropical and temperate	East Africa <sup>‡</sup>	Temperate North America and Eurasia
Fever ≥39°C	Common	Common	Rare
Fever relapses	Multiple	Few	None
Neurologic involvement	Common <sup>§</sup>	Rare	Common
Localized skin rash	No	No	Common (erythema migrans)
Arthritis	No	No	Common
Serologic assay specificity	Fair–poor	Fair–poor	Good–excellent
Antibiotic therapy	Several doses	Single or few doses	Several doses

\*Included in *B. burgdorferi* sensu lato are *B. burgdorferi* sensu stricto, *Borrelia afzelii*, and *Borrelia garinii*.

<sup>†</sup>The reservoir for *Borrelia duttoni* may be humans in some location.

<sup>‡</sup>Louse-borne RF has a potential worldwide distribution because of its association with the human body louse.

<sup>§</sup>Common in 10% or more of patients with disseminated disease.

LB, Lyme borreliosis; LBRF, louse-borne relapsing fever; TBRF, tick-borne relapsing fever.

\*Primary reservoir for maintenance of species in nature.

<sup>†</sup>*Borrelia burgdorferi* probably invaded Europe and *I. ricinus* ticks from its North American origin.

<sup>‡</sup>*Borrelia recurrentis* probably originated in Paleartic or Afro-Tropical regions.

not free-living in the environment (Table 45-2). Viable *Borrelia* bacteria are almost always extracellular in their reservoir and vector hosts. Outside their hosts, *Borrelia* spp. are very susceptible to drying, hypotonic or hypertonic solutions, detergents, and temperatures above 41°C. *Borrelia* spp. cells have widths of approximately 0.2 µm and lengths of 10 to 30 µm; they can be visualized by dark-field or phase contrast microscopy but not standard light microscopy without special stains. In comparison to leptospires and treponemes, borrelias have fewer and larger amplitude waves.

*Borrelia* spp. are microaerophilic microorganisms and grow in a complex medium that contains, among other ingredients, rabbit serum, glucose, albumin, peptides, vitamins, a thickening agent such as gelatin, and *N*-acetylglucosamine, the building block for an arthropod's chitin exoskeleton.<sup>8,9</sup> Some *Borrelia* species have yet to be cultivated in serial passage outside of a natural or experimental host animal. After prolonged cultivation in the laboratory, *Borrelia* spp. lose their capacity to infect animals.

Although borrelias do not have lipopolysaccharides with the characteristics of true endotoxins,<sup>10</sup> they do have abundant outer membrane lipoproteins that are potent B cell mitogens and stimulators of cytokines, such as tumor necrosis

factor and other inflammatory cytokines.<sup>11</sup> The lipoproteins are anchored at their aminoterminal ends by fatty acid moieties embedded in the fluid membrane of the spirochetes.

Among spirochetes, a distinguishing feature of the genus *Borrelia* is a genome that is largely linear.<sup>12</sup> In the cell are a few to several duplicate genomes, each consisting of a linear chromosome of approximately 1000 kilobases and several types of linear and circular plasmids. All *Borrelia* species studied to date have G + C contents of approximately 30%. DNA hybridization studies and DNA sequence analyses demonstrate two major clades of *Borrelia* species: the relapsing fever group and the Lyme borreliosis group.<sup>3</sup> The latter group includes the known agents of Lyme borreliosis—*Borrelia burgdorferi*, *Borrelia afzelii*, and *Borrelia garinii*—as well as several related species not associated with human disease. A phylogeny of relapsing fever agents based on DNA sequences has confirmed in many instances a taxonomy based on biological considerations, such as specific *Borrelia*–tick associations.<sup>13</sup> The species are also characterized by the ecological region and the arthropod vector with which they are usually associated (Table 45-3). On the basis of DNA sequences, the relapsing fever clade also includes the hard tick-borne species, *B. lonestari*, *Borrelia theileri*, and *Borrelia miyamotoi*.

**Table 45-3** *Ornithodoros* Tick-Borne Relapsing Fever *Borrelia* Species

Species	Tick Vector	Geographic Distribution
<i>B. hermsii</i>	<i>O. hermsi</i>	Western North America
<i>B. turicatae</i>	<i>O. turicata</i>	Southwestern United States and northern Mexico
<i>B. venezuelensis</i>	<i>O. rudis</i>	Central America and northern South America
<i>B. hispanica</i>	<i>O. maroccanus</i>	Iberian Peninsula and northwestern Africa
<i>B. crocidurae</i>	<i>O. erraticus</i>	North Africa and Mediterranean region
<i>B. duttonii</i>	<i>O. moubata</i>	Central, eastern, and southern Africa
<i>B. persica</i>	<i>O. tholozani</i>	Western China, northern India, Central Asia, Iran, and Egypt
<i>B. latyschewii</i>	<i>O. tartakovskyi</i>	Tajikistan and Uzbekistan

## EPIDEMIOLOGY

Except for the louse-borne agent *Borrelia recurrentis*, *Borrelia* species are transmitted by ticks.<sup>14</sup> The vectors of tick-borne relapsing fever are argasid ticks of the genus *Ornithodoros*. *Ornithodoros* ticks pass through more than one nymphal stage between the larval and adult stages; Figure 45-1 shows several sizes of *Ornithodoros turicatae*. Most species of argasid ticks feed on a single or a very limited number of types of animal. *Ornithodoros* ticks are noted for their longevity, up to 15 to 20 years, and their ability to survive without a blood meal for several years.<sup>1</sup> Transovarial transmission by their argasid vectors is common among tick-borne *Borrelia* species, thus providing for survival in an environment during periods when vertebrate hosts are absent or sparse. Reservoirs of the relapsing fever *Borrelia* species include a variety of mammals, most commonly rodents, but may include birds as well. The natural reservoir for the tick-borne species *Borrelia duttoni* appears to be humans.

*Ornithodoros* ticks feed for less than 30 minutes, usually at night. Most people are not aware of their bite. The only sign of an *Ornithodoros* tick bite may be a small red or violaceous papule with a central eschar that appears within a few days. Spirochetes are present in the salivary gland at the onset of feeding, and the pathogens enter the host with the saliva soon after the tick begins to feed. The risk of relapsing fever after a single bite of an infected tick is 50% or greater.

Tick-borne relapsing fever of humans occurs in the Palearctic, Nearctic, Afro-Tropical, and Neotropical ecological regions. Endemic infections have not been well documented in the Indo-Malayan, Australasia, or Oceania ecological regions. Reports of relapsing fever from areas with rain forests or monsoon forests are probably attributable to louse-borne infection or the importation of infected ticks with livestock.

In the United States and Canada, most cases of autochthonous relapsing fever are due to *B. hermsii* and *B. turicatae*.<sup>15,16</sup> Although vectors and reservoirs for these species are widely distributed in the western United States, human disease incidence is highly focal. Among 450 cases of relapsing fever identified in the United States over 14 years, 13 counties accounted for half of the cases.<sup>17</sup> *Ornithodoros hermsii*, the vector of *B. hermsii*, is found in forested mountains at elevations ranging from 1000 to 2700 m, depending on the latitude,

throughout the western United States and British Columbia. Common hosts for *O. hermsii* are chipmunks and squirrels. Most cases of *B. hermsii* infection can be traced to sleeping in or near cabins and rustic houses that have rodents nesting in the roof, under eaves, in walls, under porches, or in wood piles.

*Ornithodoros turicata*, the vector of *B. turicatae*, is found in desert, semidesert, and scrub landscapes of the southwestern and south-central United States, as well as in drier areas of central Mexico and an isolated focus in Florida. *Ornithodoros turicata* ticks reside in rodent burrows or in caves and overhanging rock ledges that shelter larger animals. In Mexico, *O. turicata* has also been found in human habitats, especially those with pigsties. Humans become infected with *B. turicatae* by entry into caves, crawling under houses, or sleeping in structures with walls infested with *O. turicata*. *Borrelia parkeri* is closely related to *B. turicatae* on the basis of DNA sequences, and its enzootic distribution partially overlaps that of *B. turicatae*.<sup>13</sup> However, human infections with *B. parkeri* are rare, probably because humans seldom encounter the tick vector *Ornithodoros parkeri*. *Ornithodoros talaje*, the vector of *Borrelia mazzottii*, overlaps the distribution of *O. turicata* in the southwestern United States and extends as far as south as Guatemala. Tick-borne relapsing fever has been reported in Panama, where the natural hosts include monkeys, opossums, and armadillos. The vector in Panama as well as Venezuela and Colombia is *Ornithodoros rudis*, and the agent is *Borrelia venezuelensis*.

Tick-borne relapsing fever remains a common infection of rural village areas of some areas of sub-Saharan Africa.<sup>18,19</sup> Many cases are associated with human habitats with thatched roofs or mud walls or floors. In East, South, and Central Africa, most cases have been attributable to *Borrelia duttoni* transmitted by *Ornithodoros moubata*. A cause of tick-borne relapsing fever in the arid Sahel region of West Africa is *Borrelia crocidurae*.<sup>18</sup> Human infections from *Borrelia persica*, *Borrelia latyshevi*, and *Borrelia hispanica* also continue to occur in central Asia, Iran, North Africa, and the Middle East. The range of *B. persica* extends from the Mediterranean area and the Middle East to central Asia.<sup>20</sup> *Borrelia persica*'s vector, *Ornithodoros tholozani*, lives in houses and buildings, as well as burrows and caves. In central Asia and the Caucasus region, *B. latyshevi* is a less likely agent of relapsing fever because its vector ticks rarely inhabit human dwellings. In the past, the range of *B. hispanica* included the Iberian Peninsula. Endemic relapsing fever has been reported again in Spain, but it is caused by a *Borrelia* sp. that may be distinct from *B. hispanica*.<sup>21</sup>

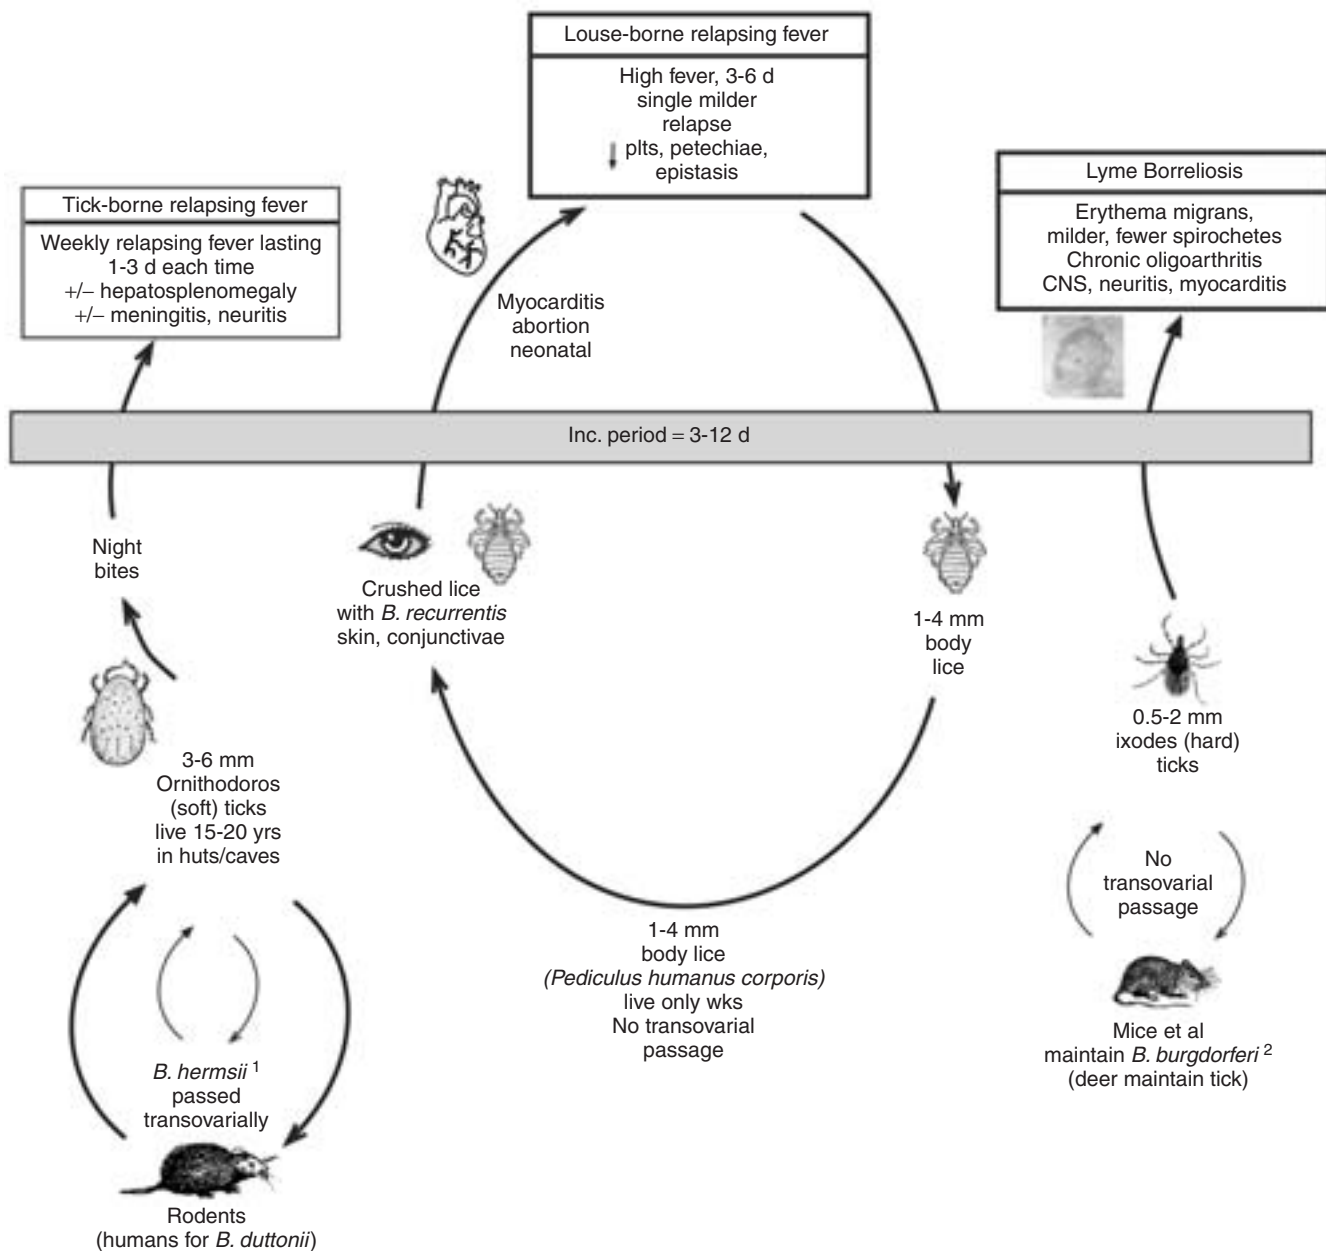

## Louse-Borne Relapsing Fever

The vector of epidemic relapsing fever is the body louse, *Pediculus humanus corporis*, and possibly the head louse *P. humanus capitis*, which only feed on humans in nature.<sup>22</sup> Nonhuman primates can be experimentally infected with *B. recurrentis*, but it appears that humans are the critical reservoirs for maintenance of the pathogen in nature. After entering the midgut of the feeding louse, the *B. recurrentis* move to the hemolymph, where they may persist for the approximately 3-week life span of the louse. They do not migrate to the salivary glands or appear in the feces. Instead, humans become infected with *B. recurrentis* when they crush an infected louse with fingers or "pop" one with their teeth. The organism is

**FIGURE 45-1** Nymphal and adult *Ornithodoros turicata* ticks collected from a cave in which several people acquired tick-borne relapsing fever.

**Tick- and louse-borne relapsing fevers and Lyme borreliosis**  
**[*Borrelia hermsii* (et al)<sup>1</sup>, *recurrentis* and *burgdorferi*<sup>2</sup>]**

introduced at the bite site, the skin of the crushing fingers, the conjunctivae when people rub their eyes, or through the mucous membranes of the mouth.

*Borrelia recurrentis* infection still occurs in the Horn of Africa, particularly in the highlands of Ethiopia, where it has been endemic for decades.<sup>23</sup> Transmission is highest during the rainy season when the poor gather together in shelter, and infected lice move from one person to another. As reflected by such colloquial names as “famine fever” and “vagabond fever,” factors that predispose to louse-borne relapsing fever epidemics include famine, war, and refugees. Precipitating conditions for outbreaks are crowding, limited changes of clothing, and lack of access to washing. Millions of cases of louse-borne relapsing

fever occurred during the disrupted times of the two world wars of the 20th century.<sup>24</sup>

### Lyme Borreliosis

The vectors of Lyme borreliosis agents are species of the *Ixodes* genus of hard ticks: *Ixodes scapularis* in the eastern United States, *Ixodes pacificus* in the western United States, *Ixodes ricinus* in Europe, and *Ixodes persulcatus* across Russia to northern Asia.<sup>3,25</sup> *Borrelia burgdorferi* is the sole agent in North America. This species has also spread from North America to Europe, but most cases in Europe, Russia, and northern Asia are caused by *B. afzelii* or *B. garinii*. Transovarial transmission

of the pathogen by the *Ixodes* spp. ticks is rare or nonexistent. Ticks usually acquire the infection when they feed as larvae or nymphs on small mammals or birds. After the molt, the nymphs or adults feed on other mammals and birds, thus perpetuating the *Borrelia* spp. in nature. The usual hosts for the adult ticks are large mammals, such as deer. Humans most commonly become infected through the bite of nymphs, which are small enough to go unnoticed. Unlike argasid ticks, which feed for only short periods of time and transmit the spirochetes from the start of feeding, ixodid ticks feed for several days before dropping off. *Borrelia burgdorferi* and other Lyme borreliosis species must migrate from the midgut to the salivary glands over 1 or 2 days before they begin to enter the host.

Lyme borreliosis is the most common vector-borne disease in the United States, primarily in the northeastern and north central regions, and throughout much of Europe.<sup>2,26</sup> The risk of infection is highly focal, though, and it depends on the characteristics of the environment and the degree of exposure to infected nymphs. A canopied forest with an undergrowth of grass and low shrubs is a typical landscape. Humans come in contact with ticks through recreational and work activities in these environments and also around their homes, which may abut forests and wood stands. Unlike some *Ornithodoros* species, the *Ixodes* ticks that transmit Lyme borreliosis do not reside in dwellings.

## DISEASE

The clinical hallmark of relapsing fever is the sudden onset of two or more episodes of fever spaced by afebrile periods of greater well-being (Table 45-4).<sup>24,27–29</sup> The temperature may reach 43°C and is usually above 39°C. In the louse-borne form, the first episode of unremitting fever lasts 3 to 6 days and is typically followed by a single milder episode. During tick-borne relapsing fever, there are multiple febrile periods of 1 to 3 days each, as observed in the temperature pattern of two cases (Fig. 45-2). In both forms of relapsing fever, the intervals between fevers are generally from 4 to 14 days. The first fever episode ends by crisis, which is characterized by rigors, hyperpyrexia, and elevations of pulse and blood pressure over approximately 15 to 30 minutes. This phase is followed by a few to several hours of profuse diaphoresis, falling temperature, and hypotension. Deaths from untreated

**FIGURE 45-2** A and B, Temperature curves in two cases of tick-borne relapsing fever. The exposure to ticks occurred 1 week before onset of first fever. The Xs on the curves indicate when temperatures were taken. Wright-stained blood smears of the patient in (B) were examined and were assessed as positive (+) or negative (–) with respect to the presence of spirochetes (see Fig. 45-4).

relapsing fever are most common during the crisis and its immediate aftermath.

Accompanying the first and subsequent fevers are headache, neck stiffness, arthralgia, myalgia, and nausea. The person with relapsing fever may complain of dizziness and have an unsteady gait. On examination, the patient may be delirious or apathetic. Sometimes, the initial presentation is stupor or coma. A nonproductive cough is common during louse-borne relapsing fever and may, in combination with high fever and myalgias, suggest influenza.

Most patients with relapsing fever have splenomegaly, which may present as abdominal or left shoulder pain. A frequent feature in early descriptions of relapsing fever was jaundice. More than half of patients with louse-borne relapsing fever and approximately 10% of patients with tick-borne relapsing fever have enlarged livers and clinical or laboratory evidence of hepatitis. There are elevated levels of hepatic transaminases and unconjugated bilirubin and also moderately prolonged prothrombin and partial thromboplastin times.

**Table 45-4** Clinical and Laboratory Features of Tick-Borne RF, Louse-Borne RF, and Lyme Borreliosis

Characteristic	Tick-Borne RF	Louse-Borne RF	Lyme Borreliosis
Fever $\geq 39^{\circ}\text{C}$	Common	Common	Rare
Duration without treatment	Days–weeks	Days	Weeks–years
Fever relapses	Multiple	Few	None
Local skin rash	No	No	Common
Neurologic involvement	Common	Rare	Common
Joint involvement	No	No	Common
Spirochetes on blood smear	Yes	Yes	No
Antibiotic therapy	Several doses	Single or few doses	Several doses
Jarisch–Herxheimer reaction	Moderate	Moderate–severe	Mild

RF, relapsing fever.

Cholestasis is not prominent. If the albumin concentration is low, it is more likely the consequence of preexisting malnutrition or ongoing leakage of fluids into tissues than the hepatic dysfunction.

In louse-borne relapsing fever, epistaxis and skin petechiae and ecchymoses are common. They probably are attributable to thrombocytopenia, impaired production of clotting factors by the liver, and/or blockage of small vessels by aggregates of spirochetes. Epistaxis and petechiae are less common in tick-borne relapsing fever than in louse-borne relapsing fever. Platelet counts may fall below 50,000/ $\mu$ L. Leukocyte counts are usually in the normal range or only slightly elevated; there may be leukopenia during the crisis. A mild-to-moderate normocytic anemia is common.

Although louse-borne relapsing fever patients often present with delirium, apathy, or stiff neck, these are more likely the effect of the bacteremia than specific invasion of the central nervous system.<sup>30</sup> Direct neurologic involvement is more common in tick-borne relapsing fever. Meningitis and meningoencephalitis are serious consequences of this invasion. There may be residual hemiplegia or aphasia. Cranial neuritis, most commonly of the seventh or eighth cranial nerves, typically first appears during the second or third febrile period of tick-borne relapsing fever. The presentation is unilateral or bilateral Bell's palsy or deafness. Other neurologic manifestations during tick-borne relapsing fever are radiculopathy and myelitis. Unilateral or bilateral iridocyclitis or panophthalmitis may leave the patient with permanent visual impairment.

Myocarditis appears to be common in louse-borne and tick-borne relapsing fever and may be the proximate cause of death in many cases.<sup>31,32</sup> The most common evidence of myocarditis is gallops on cardiac auscultation and a prolonged QTc interval by electrocardiogram. Some patients have cardiomegaly and pulmonary edema on chest radiographs.

Relapsing fever during pregnancy frequently leads to abortion or stillbirth. There may be transplacental transmission of the infection, or a newborn may be infected at birth.<sup>33,34</sup> Congenital malformations as a consequence of relapsing fever have not been reported.

During early infection with *B. burgdorferi*, *B. afzelii*, or *B. garinii*, the frequent skin manifestation is erythema migrans, a erythematous patch or target-like skin lesion at the site of the tick bite.<sup>35</sup> During dissemination of the infection, erythema migrans lesions may appear in numerous locations. Temperatures of 39°C or higher are uncommon during Lyme borreliosis. The greatest morbidity with Lyme borreliosis occurs in patients with late or chronic infections (i.e., those lasting several weeks to years).<sup>2</sup> In these patients, there is chronic oligoarthritis, debilitating dysfunction of the central and/or peripheral nervous system, or a persistent inflammatory skin disorder.

In fatal cases of relapsing fever, the usual gross findings are widespread petechiae, enlarged spleen and liver, and an edematous, congested brain.<sup>24,27,30</sup> The most common general findings on histologic examination of autopsy cases are swelling of endothelial cells, microvascular leakage, perivascular mononuclear cell infiltrates, microabscesses, and hemorrhages. Fatal cases of louse-borne relapsing fever frequently have myocarditis with histiocytic infiltrates and microhemorrhages. The spleen and liver, but not the kidneys or adrenals, often

have focal areas of necrosis. Although bleeding is a common complication of louse-borne relapsing fever, evidence of intravascular coagulation is not prominent.

The spirochetes can be detected in tissue sections with Warthin–Starry or modified Dieterle silver stains or by immunofluorescence.<sup>36</sup> Borrelias are primarily extracellular organisms. They move through or between endothelial cells as they leave the blood for tissues, but they do not appear to proliferate in these or phagocytic cells. The spirochetes are usually found in perivascular locations, sometimes as tangles of bacteria. In autopsy cases and experimentally infected animals, spirochetes are commonly found in the spleen, liver, brain, eye, and kidney. In the brain, the spirochetes are around the meninges.<sup>30,37</sup> In general, the severity of relapsing fever directly correlates with the number of spirochetes in the blood.<sup>38</sup>

Fatalities from Lyme borreliosis only are extremely rare.<sup>2</sup> The usual pathologic specimen is a skin biopsy, which if taken from the leading edge of the expanding skin rash can reveal spirochetes by silver stain or immunofluorescence.<sup>36</sup> Biopsies of synovial tissue of patients with frank arthritis reveal acute and chronic inflammation with proliferative synovium.<sup>39</sup> The presence of spirochetes in joint tissue can be demonstrated by polymerase chain reaction but almost never by microscopy.

## PATHOGENESIS AND IMMUNITY

A *Borrelia* infection of humans almost always begins with contact with a tick or louse bearing the spirochetes. Less commonly, the disease is acquired through accidental inoculation of infected blood; by contact of blood with abraded or lacerated skin, mucous membranes, or the conjunctiva; or, rarely, by transplacental transmission from mother to fetus.<sup>33,34</sup> Transmission to humans by aerosol, fomites, human saliva, urine, feces, or sexual contact has not been documented.

A single spirochete is sufficient to initiate relapsing fever.<sup>40</sup> Having gained access to the blood, the organisms multiply there at a rate of one cell division every 6 to 12 hours until they number 10<sup>5</sup> to 10<sup>8</sup> per milliliter of blood. The incubation period between the exposure and the onset of fever is 3 to 12 days. From the blood, the spirochetes may invade the central nervous system, eye, liver, and other organs. Persistence of the spirochetes in the blood for up to several weeks is achieved by the population staying one step ahead of the host's immune response through the strategy of multiphasic antigenic variation.<sup>41,42</sup>

Recurrence of fever after the initial and subsequent immune responses is the result of regrowth of the spirochete population in the blood. Early microbiologists and immunologists recognized that the new crop of borrelias were antigenically distinct from the original infecting organism.<sup>43</sup> The populations that predominated during each relapse were assigned different serotype names. For example, a rat infected with serotype A had serotypes B and C in the blood during the first and second relapse, respectively. However, the order of serotype appearance is not absolutely fixed: Sometimes, serotype C may follow serotype A instead of serotype B in the relapse sequence. Characteristically, antiserum to serotype A could passively protect mice from infection with serotype A but not serotypes B or C. Similarly, antisera against serotypes C or B were effective against the homologous serotype but not against others.

The varying antigens that determine serotype identity are a set of outer membrane lipoproteins called variable membrane proteins as a group. These proteins are of two sizes: variable small proteins (Vsps) of approximately 20 kilodaltons and variable large proteins (Vlps) of approximately 40 kilodaltons. A single strain of *B. hermsii* may be capable of producing 30 to 40 different variable major proteins, about equally divided in number between Vsps and Vlps. There can be as little as 30% identity in amino acid sequences between two different variable major proteins of the same strain of a relapsing fever *Borrelia* sp., a feature that accounts for the lack of cross-reactivity between antisera.<sup>44</sup>

There is a complete or near-complete variable membrane protein gene (*vmp*) for each Vsp or Vlp protein. In any single cell at any given time, only one *vmp* gene is expressed, usually at a site near the end of a linear plasmid. The other 30 or 40 *vmp* genes in the genome are silent in their storage locations on other linear plasmids. The expression site, in distinction from the silent sites, has a promoter in front of the *vmp* gene. A different *vmp* gene spontaneously replaces the one at the expression site at an estimated frequency of  $10^{-4}$  to  $10^{-3}$  per cell generation.<sup>45</sup> The newly appearing serotype is still in low numbers at the time the immune system responds to the first serotype with an outpouring of antibodies and, thus, escapes as the original infecting serotype is cleared from the blood.

There are two ways in which a *vmp* gene at the expression site is replaced by another. The most common mechanism is a nonreciprocal, unidirectional recombination between two linear plasmids.<sup>41,42</sup> A simplified representation of such a switch in these genes is shown in Figure 45-3. The recombination has the features of a gene conversion: The unchanged donor sequence is a silent *vmp* and the target sequence is the *vmp* gene at the expression site. The boundaries for the recombination are regions of sequence identity between silent and expression sites around and flanking the 5' and 3' ends of the expressed and silent genes.

The second mechanism by which a new *vmp* gene is expressed is an intramolecular rather than the intermolecular recombination between two plasmids. For the second mechanism to occur, there must be an untranscribed *vmp* gene downstream from the expressed gene and in the same orientation.<sup>46</sup> A deletion between short direct repeats at the 5' ends of each of the two genes effectively excises the sitting gene.

**FIGURE 45-3** Schematic representation of molecular events in an antigenic switch from serotype W (white) or serotype G (gray) in relapsing fever *Borrelia* spp. In this switch, there is an intermolecular gene conversion in which the donor sequence is a silent *vmp* gene in a tandem array of silent genes, which are denoted by white, black, or dark or light gray boxes, on a linear plasmid. The target sequence is an extra copy of the white *vmp* gene that is next to the telomere (o) of another linear plasmid and downstream from a promoter. The light gray *vmp* gene at the silent location is unchanged in the recombination.

The one behind moves up with deletion to take its place next to the promoter. After this deletion, the newly expressed gene is susceptible to additional small gene conversions that provide further diversity of the *vmp* genes.

Variable membrane proteins also have a role in tissue localization during infection. Within a given species, certain serotypes can invade the brain, whereas other serotypes, identical but for the variable membrane protein, cannot.<sup>47</sup> Some species of *Borrelia*, such as *B. duttoni* in Africa and *B. turicatae* in North America, are particularly neurotropic.<sup>30</sup>

Lyme borreliosis begins as a local infection, which manifests as a skin rash approximately 1 or 2 weeks after a tick has attached for at least 24 hours.<sup>2,48</sup> In the skin, the spirochetes move centrifugally, thus enlarging the diameter of the lesion over several days to weeks. In many patients, the borrelias also circulate in the blood during acute infection but at a density that is undetectable by light microscopy of unconcentrated blood. If fever occurs during Lyme borreliosis, it is mild. During the bacteremia, the infection disseminates to other organs and tissues, commonly the joints, heart, and nerves and brain. Late manifestations of Lyme borreliosis are the result of persistence of spirochetes and the provocation of inflammation in the tissues and organs, mainly the brain and nerves, skin, heart, and large joints, rather than the reappearance of spirochetes in the blood. The pathogen's persistence, albeit in low numbers, in tissues occurs in the face of a continued antibody response and appears to be the consequence of antigenic variation in a set of surface lipoproteins—the Vls proteins—that are homologous to the Vlp proteins of relapsing fever species.<sup>41</sup>

In animals infected with relapsing fever *Borrelia* spp., immunoglobulin M (IgM) antibodies alone are sufficient to limit or eliminate infection from the blood.<sup>49,50</sup> Experimental animals with deficient T cell function, such as nude mice, clear spirochetes from the blood as effectively as their immunocompetent counterparts.<sup>51</sup> Whether T cells play a more important role in long-term protection from infection or in control of the infection in the central nervous system is not known. Because specific antibodies, even Fab monomers, to outer membrane proteins can kill borrelias in the absence of complement or phagocytes,<sup>52</sup> deficiencies in the latter immune effectors may not hinder clearance of borrelias from the blood. Immune deficiencies that do increase severity of relapsing fever in experimental animals are the absence of the spleen and impaired B-cell function.

During infection, animals and human patients have antibodies to a number of different components of spirochetes, but only those directed against the Vsps and Vlps appear to be effective in controlling infection.<sup>45</sup> Antibodies to flagella as well as other components of the *Borrelia* sp. are found in patients convalescent from relapsing fever, but these antibodies do not provide protection by passive immunization. The immune response is often not successful in clearing borrelias from the brain, cerebrospinal fluid, or eye.<sup>30</sup> In these locations, relapsing fever spirochetes, much like *Treponema pallidum*, can persist for years.

Infection with *B. burgdorferi* or another Lyme borreliosis agent is more severe, in terms of tissue inflammation, in mice with profound immune deficiencies, but the infection is not fatal.<sup>2</sup> Among immunocompetent mice, the degree of tissue pathology and spirochete burden is determined by genetic factors of both the host and the pathogen.<sup>48</sup> Experimental animals can be passively protected by immune sera alone.

In some cases, depending on the specificities of the antisera, administration of immune sera can clear infection. Although cell-mediated immunity to *B. burgdorferi* appears not to play a necessary or even sufficient role in an effective immune response to infection or vaccination, T cell responses to a pathogen or host antigen may be responsible for a form of reactive arthritis of one or a few large joints that a minority of untreated patients in North America experience.<sup>39</sup>

## DIAGNOSIS

Recurrent fevers at intervals of a few to several days suggest the diagnosis of relapsing fever. If these are accompanied by the crisis phenomenon—hepatomegaly or splenomegaly, thrombocytopenia with normal white count, cranial neuritis in the case of tick-borne relapsing fever, or jaundice and petechiae in the case of louse-borne relapsing fever—and an epidemiologic history of exposure to lice or soft-bodied ticks, then relapsing fever is highly likely. In the absence of a full constellation of typical features, relapsing fever may be confused with rickettsioses, malaria, typhoid fever, brucellosis, Colorado tick fever, dengue, leptospirosis, rat-bite fever, or meningococcemia, depending on the epidemiologic circumstances. Patients with louse-borne relapsing fever may have epidemic typhus as well. In early Lyme borreliosis, there is usually, but not always, a prominent localized erythematous rash and mild fever. Late Lyme borreliosis may mimic a number of other infectious and noninfectious disorders.<sup>2</sup> The few geographic areas where both Lyme borreliosis and relapsing fever occur are far western North America and some areas bordering the Mediterranean.

If the diagnosis of relapsing fever is suspected, a smear or wet mount of the blood should be prepared during a febrile period. Once the temperature is declining or has returned to the normal range without the aid of antipyretics, visual detection of spirochetes in blood is very unlikely. Giemsa or Wright stains of a methanol-fixed thin smear usually reveal the spirochetes if the concentration of microorganisms in the blood is greater than  $10^5$  per milliliter (Fig. 45-4).

**FIGURE 45-4** A single *Borrelia hermsii* spirochete in a Wright-stained thin blood smear of a case of tick-borne relapsing fever.

In hospitals and clinics with automated procedures for blood smear analysis, a manual examination of the blood smear should be requested. As many as 200 oil immersion fields should be viewed before judging the smear negative.

With a thick smear, concentrations of  $10^4$  or more organisms per milliliter of blood can be detected. If Giemsa or Wright stain is used, the slide should first be dehemoglobinized, such as with 0.5% acetic acid. This step can be omitted if the smear is treated with acridine orange<sup>53</sup> or fluorescein-labeled anti-*Borrelia* antibody<sup>45</sup> and then examined under ultraviolet light.

Phase contrast or dark-field microscopy reveals motile spirochetes in blood diluted in phosphate-buffered saline under a cover slip and examined at approximately  $400\times$  magnification. Coiling, uncoiling, and bending movements of the spirochetes as they swim among the erythrocytes are telltale signs. Centrifugation of the anticoagulated blood in a capillary tube and examination of the buffy coat by microscopy improve the limit of detection of microscopy to  $10^3$  spirochetes per milliliter of blood.<sup>54,55</sup>

When relapsing fever is suspected but spirochetes are not directly visualized, inoculation of blood or cerebrospinal fluid into young mice or rats may reveal a *Borrelia* sp.<sup>56</sup> Most inbred or outbred strains are suitable for this purpose. Infection of the mouse can be enhanced by sublethal gamma irradiation, treatment with cyclophosphamide, the severe combined immunodeficiency phenotype, or splenectomy.<sup>45,47,57,58</sup> The tail vein, saphenous vein, or orbital sinus blood of the inoculated mice should be examined daily for the presence of the spirochetes for 7 days.

In vitro cultivation is an alternative to animal inoculation for recovery of the organism from blood, cerebrospinal fluid, or tissues, but this is not a widely available procedure. Kelly's medium and its most commonly used derivative, BSK medium, support the growth of most *Borrelia* spp.<sup>59-61</sup> Selection from contaminants is achieved by supplementation of the medium with rifampin, phosphomycin, aminoglycosides, and/or amphotericin B. Tubes of medium are inoculated with several drops of blood or other specimen and incubated at  $34^\circ$  to  $36^\circ\text{C}$  in tightly capped tubes for up to 2 weeks. Samples of the cultures are examined every day or other day by dark-field or phase contrast microscopy. More rapid than culture for direct detection is the polymerase chain reaction, which has been used to study *B. hermsii* and *B. turicatae* in blood, brain, cerebrospinal fluid, and joint tissues of mice<sup>38</sup> and to confirm *B. duttonii* infection of humans.<sup>19</sup>

Serologic assays have seldom been of value for the confirmation of relapsing fever because of lack of standardization, limited availability, and generally low specificity of whole cell assays. Elevated titers of antibodies that bind to the *Proteus* OX-K antigen in the Weil-Felix agglutination assay occur in relapsing fever,<sup>62</sup> but this assay is less commonly offered than in the past. Enzyme-linked immunosorbent assay (ELISA) and immunofluorescence assay (IFA), which are based on whole cells, are available at some reference laboratories. They are of greatest diagnostic value when paired (i.e., acute and convalescent sera) and changes in titer are assessed. Without access to these resources, the more widely available ELISA assay for antibodies to *B. burgdorferi* may provide enough cross-reactivity that convalescent sera from some relapsing fever patients will give positive reactions. For these ELISA results to be considered supportive of the diagnosis of relapsing fever, the Western blot

assay for Lyme borreliosis and reagin-based and treponeme-specific assays for syphilis should be negative. An immunoassay using a recombinant form of GlpQ protein, which is found in relapsing fever *Borrelia* spp. but not in the LB *Borrelia* spp., demonstrated higher specificity than whole cell assays in studies of both tick-borne and louse-borne relapsing fever.<sup>63,64</sup>

In contrast to relapsing fever, laboratory confirmation of the diagnosis of Lyme borreliosis usually rests on measurement of antibodies to a Lyme borreliosis *Borrelia* spp. and not on direct recovery or detection of the agent.<sup>65</sup> Even during early infection, when the organisms are disseminating, organisms cannot be detected by microscopy of the blood. There are two options for serologic testing: (1) a whole cell-based ELISA followed by confirmatory immunoblot for those samples with positive or borderline reaction and (2) a subunit ELISA based on a conserved region of Vls proteins of *B. burgdorferi*. The sensitivity and specificity of the so-called “two-tiered” approach and the subunit assay are approximately the same. The serologic assays do not have a place as screening tests for Lyme borreliosis because of their low predictive value in situations in which the a priori likelihood of the Lyme borreliosis is low. Unlike syphilis, for which screening tests may be justified for disease control and prevention, there is no evidence of person-to-person transmission of *B. burgdorferi*.

Analysis of the cerebrospinal fluid is indicated in cases of suspected relapsing fever or Lyme borreliosis when there are signs of meningitis or meningoencephalitis.<sup>30</sup> Documentation of a mononuclear pleocytosis and/or mildly to moderately elevated protein levels in the cerebrospinal fluid provides justification for use of intravenous antibiotic therapy of tick-borne relapsing fever and Lyme borreliosis. Lumbar puncture analysis under these conditions also rules out most other non-viral infectious causes of meningitis. Standard bacterial, mycobacterial, and fungal cultures of the cerebrospinal fluid are negative if the cause of the disease is relapsing fever or Lyme borreliosis.

## TREATMENT AND PROGNOSIS

Relapsing fever was one of the first infections to be treated with an antimicrobial agent; Paul Ehrlich and colleagues administered organic arsenicals to patients with relapsing fever, and these medications were used for this purpose until the discovery of penicillin and tetracycline. Since that time, these antibiotics have been the drugs of choice for this and other *Borrelia* infections. The minimum inhibitory concentrations of penicillin and tetracycline for *Borrelia* spp. in broth medium are less than 0.1 µg/mL.<sup>9,66,67</sup> *Borrelia* spp. are also susceptible to cephalosporins, macrolides, chloramphenicol, coumermycins, and vancomycin,<sup>68</sup> but there is less laboratory and clinical experience with these antibiotics. *Borrelia*s are not susceptible to rifampin, metronidazole, and sulfa drugs and are relatively resistant to most quinolones and aminoglycosides. However, there is no evidence that *Borrelia* spp. have acquired resistance to any antibiotics. In the case of relapsing fever, the effectiveness of the antibiotic therapy can be assessed by observing the clearance of spirochetes from the blood. Within 4 to 8 hours of the first dose of an effective antibiotic, most patients will no longer have detectable spirochetes in the blood.

Single doses of 100 mg of doxycycline, 500 mg of tetracycline, or 500 mg of erythromycin stearate or ethyl succinate are

effective oral antibiotic treatment for adults with louse-borne relapsing fever.<sup>69–71</sup> For all children, the oral dose of erythromycin is 12.5 mg kg<sup>-1</sup> up to 500 mg. For children older than 8 years of age, the oral dose of doxycycline is 2 mg kg<sup>-1</sup> up to 100 mg, and the oral dose of tetracycline is 12.5 mg kg<sup>-1</sup> up to 500 mg. An alternative single-dose oral treatment is chloramphenicol at 500 mg for adults and 12.5 to 25 mg kg<sup>-1</sup> up to 500 mg for children.<sup>72</sup> The overall recurrence rate after antibiotic treatment is less than 5%. Tetracyclines appear to have better efficacy and are preferred over erythromycin, except for pregnant and nursing women and for children younger than 9 years old. When the patient cannot take tetracycline by mouth, the intravenous dose is 250 or 500 mg for adults. Parenteral treatment with intramuscular penicillin G. procaine is 600,000 to 800,000 units for adults and 400,000 units for children. If louse-borne typhus is suspected, the recommended antibiotics are doxycycline or chloramphenicol, but single doses will not be sufficient.

Tick-borne relapsing fever cases occur either sporadically or in limited outbreaks. Although the evidence on management is mostly anecdotal, accumulated clinical experience indicates that there is a recurrence rate of 20% or higher after single-dose treatment of tick-borne relapsing fever.<sup>27,73,74</sup> From their residence in the brain, protected by the blood–brain barrier, tick-borne relapsing fever spirochetes can reinvoke the blood once antibiotic levels have declined below minimum inhibitory concentrations.<sup>68,75</sup> The preferred treatment for adults, therefore, is tetracycline 500 mg or 12.5 mg kg<sup>-1</sup> orally every 6 hours for 10 days, or doxycycline 100 mg twice daily for 10 days. When tetracyclines are contraindicated, the alternative is erythromycin 500 mg or 12.5 mg kg<sup>-1</sup> orally every 6 hours for 10 days. If a  $\beta$ -lactam antibiotic is given, it should be administered intravenously rather than orally, especially if central nervous system involvement is suspected or confirmed by examination. Three million units of penicillin G every 4 hours or 2 g ceftriaxone once a day or in two divided doses for 10 to 14 days for adults is effective intravenous treatment for Lyme borreliosis and from animal studies would likely also be effective for relapsing fever with neurologic involvement.

In general, the treatment of Lyme borreliosis is similar to that of tick-borne relapsing fever.<sup>2,76</sup> Two recommended oral therapies for adults with uncomplicated, early disease are doxycycline, 100 mg twice daily, or amoxicillin, 500 mg three times daily, for 14 to 21 days. When central nervous system involvement is documented or suspected, parenteral antibiotics as described in the preceding paragraph are recommended. In some cases of Lyme borreliosis, either oral or parenteral antibiotics are continued for up to 1 month.

## Jarisch–Herxheimer Reaction

Relapsing fever is one of the few infections for which antibiotic therapy poses a significant risk of death or further morbidity, for reasons other than anaphylaxis or overdose. Within a few hours of the first dose of an antibiotic of most any type, 80% to 90% of patients with louse-borne relapsing fever and 30% to 40% of patients with tick-borne relapsing fever experience a worsening of symptoms.<sup>77,78</sup> In a minority of patients, the reaction is life-threatening or fatal. A mild Jarisch–Herxheimer reaction (J-HR) occurs during the first day

after start of antibiotics for some patients with early localized or disseminated Lyme borreliosis.

J-HR is essentially the same as the “crisis” that soon follows the appearance of neutralizing antibodies in the blood. In both situations, the borrelial cells are lysed, and their contents are released into the circulation. Within 1 or 2 hours, the patient experiences intense rigors and becomes restless and apprehensive. The temperature elevates 1°C or 2°C, and the pulse rate and blood pressure rise. This is followed during the next few hours by profuse sweating, exhaustion, a decline in temperature, a fall in blood pressure, and leukopenia.

In an animal model of the J-HR, the same changes in temperature and white cell count occur after treatment of infected mice with ampicillin or infusion of ruptured spirochetes. The abundant lipoproteins of the spirochetes likely act on the Toll-like receptor 2 of macrophages and other cells.<sup>11,79</sup> This ligand-receptor binding induces the release of inflammatory cytokines.<sup>80</sup> Levels of tumor necrosis factor (TNF), interleukin (IL)-6, and IL-8 increase severalfold over pretreatment levels during the J-HR in patients treated for louse-borne relapsing fever.<sup>81</sup>

Therapy with penicillin in comparison to tetracyclines has a somewhat lower risk of producing a severe J-HR,<sup>71</sup> but this may be at the cost of a delay in illness resolution and possibly a higher disease recurrence risk.<sup>71,82</sup> Administration of corticosteroids, pentoxifylline, antipyretics, or naloxone has been of limited or no benefit in reducing morbidity or mortality from J-HR. Infusion of antibodies to human TNF prior to administration of the penicillin reduced the severity of J-HR in a clinical trial,<sup>83</sup> but this treatment is very expensive.

Anticipation of the reaction and provision of monitoring or constant nursing attention will permit resuscitative measures, such as volume expansion and digoxin, to be started promptly. Placement of an intravenous line with an infusion of saline before administering the antibiotic is recommended. The pathophysiology of J-HR includes low systemic resistance and dilatation of the vasculature, increased tissue demands for oxygen from fever and inflammation, and myocardial dysfunction. If all of these aspects are addressed, for example, by increasing the blood volume, providing an inotropic agent, and reduction of core body temperature by tepid water sponge baths or acetaminophen, the chances of recovery from a severe J-HR or from a severe crisis are improved.

Untreated louse-borne relapsing fever and tick-borne relapsing fever historically have had mortality rates of 10% to 70% and 4% to 10%, respectively. With timely treatment with appropriate antibiotics, the death rates are reduced to 2% to 5% for the louse-borne form and to less than 2% for tick-borne relapsing fever. Malnourished individuals, infants, and pregnant women are at a higher risk of more severe disease. Prognosis is poorer if the patient is stuporous or comatose on admission or if there is diffuse bleeding, myocarditis, poor hepatic function, bronchopneumonia, or coinfection with typhus, typhoid,<sup>84</sup> or malaria. The mortality rate from J-HR in louse-borne relapsing fever is approximately 5%. Some patients have survived the crisis or J-HR only to die suddenly later the same day or the next, perhaps from an arrhythmia.

Mortality from Lyme borreliosis is rare and is probably attributable to cardiac conduction abnormalities during myocarditis. There have been no recorded fatalities from J-HR with Lyme borreliosis. Some patients with chronic arthritis do

not substantially benefit in the short term from one or two courses of antibiotic therapy, but many eventually show improvement.

## PREVENTION AND CONTROL

Louse-borne relapsing fever can be prevented by avoiding infestation or contact with human body and possibly head lice. Although humans are reservoirs of the infection, there is no direct human-to-human transmission, with the exception of transplacental or perinatal transmission or contact with blood. The body louse lives in clothing and only attaches to the skin when feeding. Reduction of crowding, improved personal hygiene, and better access to washing facilities greatly decreases the potential for louse-borne diseases. More specific and immediate measures for delousing patients and household or shelter contacts are bathing, shaving of the scalp, and application of one of the following: 1% lindane shampoo (Kwell) or powder; 0.5% permethrin powder; 1% permethrin soap, lotion, or shampoo; 10% DDT powder; 5% carbaryl powder; or 1% malathion powder.<sup>27,85</sup> The insecticides can be mixed with talcum powder. Infested clothes and bedding materials should be washed in water that is at least 60°C and with either soap or 7% (w/v) DDT. If possible, the clothing and bedding should then be ironed.

Log cabins and similar wood structures in forested areas are a particular risk for tick-borne relapsing fever when rodents nest in roofs, walls, and woodpiles, under eaves and porches, and in burrows under the house. In other natural environments, ticks may be in caves or natural shelters where animals sleep and nest. In inhabited areas, ticks may be in thatched roofs, mud walls, and crawl spaces under houses. In more agrarian environments, domestic animals, such as pigs, goats, and sheep, may be reservoirs for infection of humans, if the livestock are adjacent to the living quarters and the ticks have access to the human household. Sleeping on floors of buildings with suspected infestation should be avoided. Beds are preferably metal and at a distance from walls. Insecticide-impregnated mosquito nets around the bed may be useful. For entry into infested caves, DEET can be applied to the exposed skin, and permethrin can be sprayed on clothing. Efforts should be made to make structures rodent-proof.<sup>62,86</sup> Interiors of buildings infested with *Ornithodoros* ticks can be sprayed or fumigated with 0.5% diazinon, 0.5% malathion, or 0.5% lindane.

Empirical evidence suggests that when *Ornithodoros* tick bites do occur on an occasional basis, such as during exploration of a cave or vacation in a cabin located in an area endemic for tick-borne relapsing fever, prophylactic tetracycline (500 mg orally four times daily for 2 or 3 days) will reduce the risk of infection if taken within 2 days of the exposure. This regimen may also prevent illness after accidental inoculation with infected blood or culture medium in the laboratory, hospital, or clinic.

Currently, there is no vaccine for either louse-borne relapsing fever or tick-borne relapsing fever. A would-be developer of such a vaccine faces the challenge of the several serotypes that a single strain presents to the host. Until a conserved antigen is identified, the prospects for a successful vaccine are poor. A vaccine against Lyme borreliosis was approved for commercial use in the United States, but it is no longer on the market or available.<sup>26</sup>

# Leptospirosis

WUN-JU SHIEH  
CHARLES EDWARDS  
PAUL N. LEVETT  
SHERIF R. ZAKI

## INTRODUCTION

Leptospirosis is a zoonotic disease caused by pathogenic spirochetes of the genus *Leptospira*. In 1907, Stimson described the microorganism in renal tubules of a patient who died of so-called yellow fever.<sup>1</sup> The spirochete was first isolated in Japan by Inada and coworkers in 1915,<sup>2</sup> nearly 30 years after Weil described the clinical disease in 1886.<sup>3</sup> Its relatively recent discovery belies the long history of leptospirosis, which was probably known much earlier in China and Japan by names such as “rice harvest jaundice” and “autumn fever.”<sup>4,5</sup>

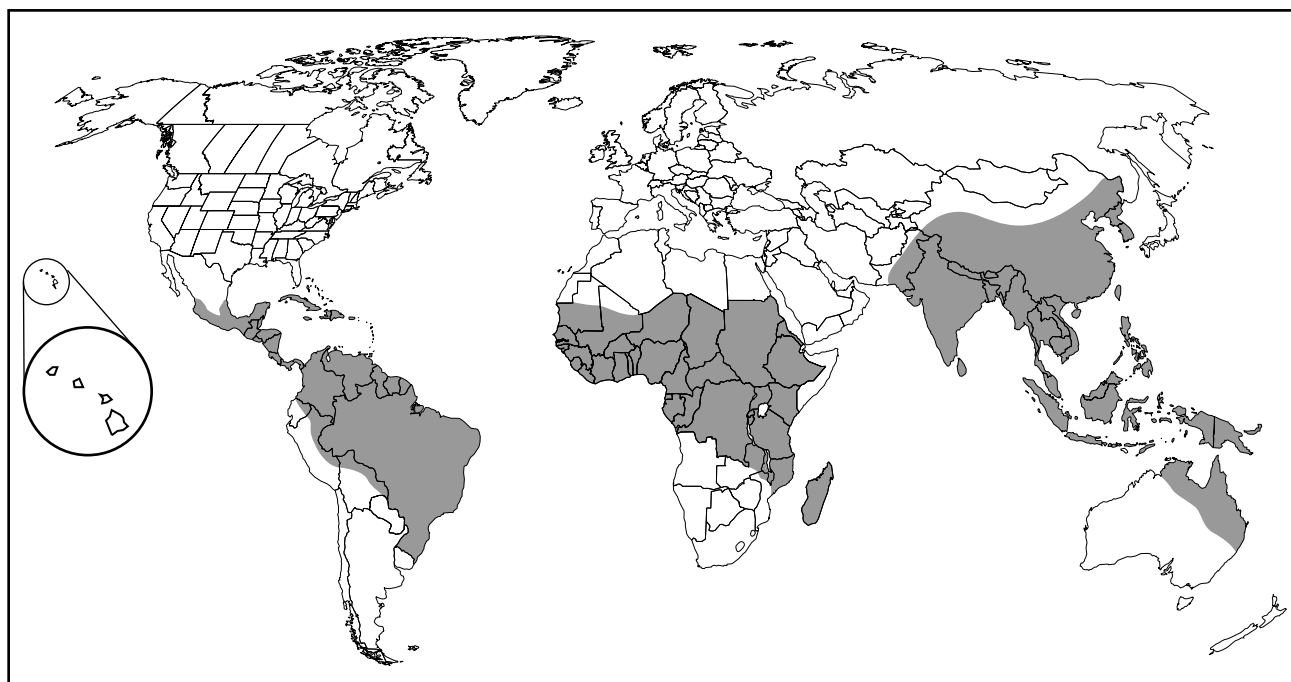

## AGENTS

Leptospire (from the Greek *leptos*, “fine,” and *speira*, “a coil”) are thin, finely coiled, filamentous spirochetes measuring 6 to

20  $\mu\text{m}$  in length and 0.1  $\mu\text{m}$  in width, with characteristic curved or hooked ends. The genus *Leptospira* contains both pathogenic and nonpathogenic strains. Traditionally, pathogenic leptospire have been included in the species *L. interrogans*, which contains at least 250 antigenically distinct variants known as serovars.<sup>6,7</sup> The genus *Leptospira* was reclassified, based on DNA relatedness,<sup>8–10</sup> into 16 species including at least 7 pathogenic species: *L. interrogans*, *L. borgpeterseni*, *L. inadai*, *L. noguchii*, *L. santarosai*, *L. weillii*, and *L. kirschneri*. Identification of *Leptospira* isolates is important because different serovars cause different clinical diseases and have different host specificities.

## EPIDEMIOLOGY

Leptospirosis is an infectious disease of worldwide distribution. Because it is most prevalent in areas where diagnostic capabilities are limited, and because its clinical presentation varies, few reliable data on its global incidence are available. Nevertheless, this disease has been described as the most common zoonosis affecting many species of wild and domestic animals, such as rodents, livestock, wild mammals, dogs, and cats.<sup>6</sup> Human infection can occur either through direct contact with infected animals or, much more commonly, through indirect contact with water or soil contaminated by the urine of infected animals.<sup>11</sup> Person-to-person transmission is extremely rare since man is a dead-end host for leptospiral dissemination.<sup>5</sup> In contrast, leptospire can survive for long periods in the renal tubules of infected animals without causing illness. Most human infections occur in young adult men and children and result from occupational or environmental exposure.<sup>11</sup> Epidemiologic studies indicate that infection is commonly associated with certain occupations, such as farmer,

*Leptospira* spp.

sewage worker, veterinarian, and animal handler. Leptospirosis can also be transmitted during recreational activities, such as hiking, picnicking, swimming, and canoeing.<sup>12–15</sup>

Leptospire can survive in untreated water for months or years, but it cannot survive desiccation or salt water.<sup>11</sup> Only sporadic cases of leptospirosis are seen in arid climates and deserts. In comparison, the disease is endemic in tropical and temperate areas, areas with heavy precipitation, and areas with high levels of subsurface water. Hence, China, Southeast Asia, Africa, and South and Central America have immense areas where the disease is endemic. Leptospirosis occurs sporadically in these areas, with a peak seasonal incidence in summer; large epidemics have been reported after periods of unusually heavy rainfall and monsoons.

## DISEASE

The incubation period of leptospirosis ranges from 2 to 26 days (usually 7 to 12). In general, it can be divided into two distinct clinical syndromes: 90% of patients present with a mild anicteric febrile illness, and 10% are severely ill with jaundice and other manifestations (Weil's syndrome). Both anicteric and icteric leptospirosis may follow a biphasic course. In the first or septicemic phase, patients usually present with an abrupt onset of fever, chills, headache, myalgias, skin rashes, nausea, vomiting, conjunctival suffusion, and prostration. The fever may be high and remittent, reaching a peak of 40°C before defervescence. Conjunctival suffusion is characteristic and usually appears on the third or fourth day (Plate 46-1). Myalgias usually involve the muscles in the calf, abdomen, and paraspinal region and can be severe. When present in the neck, myalgias may cause nuchal rigidity reminiscent of meningitis. In the abdomen, myalgia may mimic acute abdomen, leading to confusion with surgical intraabdominal emergencies.<sup>15–17</sup> The cutaneous manifestations in mild leptospirosis include transient urticarial, macular or maculopapular, erythematous, or purpuric rash.<sup>18</sup> The first phase lasts 3 to 9 days, followed by 2 or 3 days of defervescence, after which the second or “immune” phase develops.

**FIGURE 46-1** Hypopyon uveitis with posterior synechiae. (Courtesy of Dr. S. R. Rathinam, Aravind Eye Hospital, Madurai, India.)

The second phase is characterized by leptospiruria and correlates with the appearance of IgM antibodies in the serum. Fever and earlier constitutional symptoms recur in some patients, and signs of meningitis, such as headaches, photophobia, and nuchal rigidity, may develop. Central nervous system (CNS) involvement in leptospirosis most commonly occurs as aseptic meningitis.<sup>19–21</sup> Complications such as optic neuritis, uveitis,<sup>22,23</sup> iridocyclitis,<sup>24</sup> chorioretinitis,<sup>25</sup> and peripheral neuropathy occur more frequently in the immune phase<sup>26</sup> (Fig. 46-1). Prolonged or recurrent uveitis was demonstrated in 2% of patients with onset several months after symptoms of clinical leptospirosis.<sup>27</sup>

In icteric leptospirosis, persistent high fever and jaundice may obscure the two phases.<sup>26</sup> The severe form of leptospirosis is usually associated with hepatic dysfunction, renal insufficiency, hemorrhage, myocarditis,<sup>28,29</sup> and a high mortality. Hemorrhage can occur as petechiae, purpura, conjunctival hemorrhage, gastrointestinal hemorrhage, and pulmonary hemorrhage. Severe pulmonary hemorrhage has been described in China,<sup>30</sup> Korea,<sup>31</sup> and since 1996 in Nicaragua,<sup>32,33</sup> where patients died of pulmonary hemorrhage with no significant renal dysfunction or jaundice (Fig. 46-2). Other, less common manifestations of leptospirosis are generalized lymphadenopathy,<sup>32,34</sup> pharyngitis, acalculous cholecystitis,<sup>17,35</sup> and adult respiratory distress syndrome.<sup>36</sup>

Most of the routine laboratory tests show nonspecific findings. The white blood cell count can be low, normal, or elevated, but it is usually associated with a left shift. Mild anemia and thrombocytopenia are common; hemolytic anemia and disseminated intravascular coagulation have been described in severe cases.<sup>37</sup>

**FIGURE 46-2** Bilateral pulmonary infiltrates as seen in chest radiograph of a patient who died of massive pulmonary hemorrhage.

Thrombocytopenia is found in more than 50% of patients and is significantly associated with renal failure.<sup>38,39</sup> Liver, renal, and CNS involvement may be present in any combination. Liver involvement may be mild or severe, with bilirubin levels reaching 60 to 80 mg/dL in extreme cases.<sup>40</sup> Hepatomegaly occurs more often in icteric disease but is observed in as many as 15% of anicteric cases. Serum alkaline phosphatase, lactate dehydrogenase, aspartate aminotransferase, and alanine aminotransferase may all be elevated.<sup>41</sup> Usually, the levels are two or three times greater than the upper limits of normal and infrequently reach the higher ranges typical of acute viral hepatitis. Hyperamylasemia occurs frequently in severe disease, but pancreatitis is rare. Proteinuria, pyuria, hematuria, and hyaline or granular casts are common findings on urinalysis, even in the absence of renal dysfunction.<sup>42</sup> Renal function impairment is primarily a result of tubular damage; however, hypovolemia may play a critical role in the subsequent development of renal insufficiency.<sup>43,44</sup> In the cerebrospinal fluid (CSF), neutrophils usually predominate in the early course of meningitis but are surpassed by lymphocytes after the seventh day. The CSF protein level may be normal or elevated up to 300 mg/dL, while the glucose concentration is normal. Although abnormal CSF findings are reported in as many as 80% of leptospirosis cases, only half of the patients are symptomatic.

Various electrocardiographic and chest radiographic abnormalities are common in patients with leptospirosis.<sup>45,46</sup> Arrhythmias or significant cardiac irritability was documented in 35% of patients who were subjected to continuous cardiac monitoring for 24 hours.<sup>26</sup> The significant arrhythmias were atrial fibrillation, flutter, and tachycardia. Premature ventricular contractions are common and can progress to ventricular fibrillation. Echocardiograms on 88 patients in one study revealed pericarditis and small pericardial effusions in 6% of patients.<sup>26</sup> The chest radiographic abnormalities can include pulmonary edema, diffuse pneumonitis, nonsegmental or basal linear opacities, and pleural effusions.<sup>47,48</sup>

The prognosis of leptospirosis depends on the severity of the disease and associated complications. Anicteric leptospirosis usually has a good prognosis, but fatal pulmonary hemorrhage and myocarditis have been reported in anicteric cases.<sup>32,33</sup>

**FIGURE 46-3** Low-power magnification of liver that shows a portal area infiltrated with a moderate number of lymphocytes. Note prominent portal ductal and canalicular bile plugs, sinusoidal dilation, and hypertrophic Kupffer cells containing phagocytosed erythrocytes. (H&E; original magnification  $\times 50$ .)

**FIGURE 46-4** Photomicrograph of kidney showing tubular dilation and an interstitial mononuclear infiltrate. Note swelling and focal denudation of tubular epithelial lining cells. (H&E; original magnification  $\times 100$ .)

The case fatality rate for Weil's syndrome is 15% to 40% and is higher for patients older than age 60 years.<sup>49</sup>

In fatal cases, various degrees of jaundice are usually present.<sup>41</sup> Generalized petechiae or ecchymosis in the skin and most internal organs also occur commonly. Microscopically, systemic vasculitis with endothelial injury is seen. The damaged endothelial cells usually show different degrees of swelling, necrosis, and denudation. The main histopathologic changes are usually found in the liver, kidney, heart, and lungs.<sup>32,41,50-52</sup> Hepatic lesions include mild degenerative changes in hepatocytes, prominent hypertrophy and hyperplasia of Kupffer cells, erythrophagocytosis, and cholestasis<sup>53</sup> (Fig. 46-3). Focal necrosis with occasional acidophilic bodies may occur, but there is no particular zonal distribution of the necrosis. Mild to moderate mononuclear cell infiltrates are present in portal tracts. In the kidney, the main histopathologic feature is diffuse tubulointerstitial inflammation characterized by a cellular infiltrate including lymphocytes, plasma cells, macrophages, and polymorphonuclear leukocytes (Fig. 46-4). Tubular necrosis is also a common finding. Glomeruli show mild hyperplasia of mesangial cells and occasional infiltration with inflammatory cells.<sup>54</sup> Grossly, the lungs are heavy and severely congested, with focal areas of hemorrhage. Microscopically, the lungs show congestion with foci of intraalveolar hemorrhage<sup>32</sup> (Fig. 46-5). In some cases, pulmonary lesions include diffuse alveolar damage and variable degrees of airspace disorganization.

## **PATHOGENESIS**

The leptospires can penetrate abraded skin or intact mucous membranes, after which they enter the circulation and rapidly disseminate to various tissues.<sup>7</sup> Penetration and invasion of tissues are presumably accomplished through a burrowing motion produced by a pair of axial filaments and release of hyaluronidase.<sup>55</sup> The dissemination and proliferation of the spirochetes in various tissues results in a systemic illness with a broad spectrum of clinical manifestations, including fever, headache, chills, myalgia, abdominal pain, and conjunctival suffusion; more severe manifestations include renal failure, jaundice, meningitis, hypotension, hemorrhage, and hemorrhagic pneumonitis (Fig. 46-6).

**FIGURE 46-5** Lung in a fatal case with massive pulmonary hemorrhage. Extensive hemorrhage and fibrin are seen within the alveoli. Note mild interstitial inflammatory response and sloughing of bronchial epithelium. (H&E; original magnification  $\times 25$ .)

The pathogenesis of leptospirosis is not fully understood (see Fig. 46-6); there is a marked disparity between the profound clinical illness and the paucity of histologic lesions. In the septicemic (first) phase of human infections and experimental animal models, vascular injury is seen in various organs.<sup>43,56-60</sup> Spirochetes can be found in the walls of capillaries and medium- and large-sized vessels<sup>32</sup> (Fig. 46-7). The exact mechanism of vascular damage is not clear. A direct toxic effect of the leptospires has been proposed to cause the vascular injury, but no bacterial endotoxin has been demonstrated. In the immune (second) phase of illness, the host immune response, including immune complex deposition, may play a role in endothelial injury.<sup>28,38</sup>

### DIAGNOSIS

The differential diagnosis of leptospirosis depends on the epidemiology of acute febrile illnesses in the particular area.

**FIGURE 46-6** Pathogenesis and clinical characteristics of leptospirosis. (Courtesy of Nadia Zaki.)

**FIGURE 46-7** High-power magnification of a medium-size pulmonary vessel showing intact and granular forms of leptospires. Note mononuclear cells within the vessel wall and focal denudation of endothelial cells. (Immunoalkaline phosphatase staining; original magnification  $\times 25$ .)

A high index of suspicion is needed in endemic areas, and leptospirosis must be considered when a patient presents with acute onset of fever, headache, and myalgia. However, in locations where dengue fever or malaria is also present, the differentiation may be very difficult because of the similar clinical manifestations. Laboratory confirmation is crucial, especially when these diseases are occurring simultaneously during the rainy season. Other conditions to be considered in the differential diagnosis include influenza, meningitis or encephalitis, viral hepatitis, rickettsioses, typhoid fever, Kawasaki syndrome, septicemia, toxoplasmosis, brucellosis, yellow fever, hantavirus infection, and Legionnaires' disease. When the patient presents with jaundice during or after an acute febrile illness, leptospirosis must be differentiated from other causes of jaundice. The high level of bilirubin seen in Weil's disease with mild to modest elevation of transaminases assists in the differentiation from viral hepatitis, which usually has a much higher level of transaminases for any given level of bilirubin. A high serum creatine phosphokinase concentration or thrombocytopenia would also favor a diagnosis of leptospirosis. A good history should help to differentiate patients with alcoholic hepatitis.

The definitive diagnosis of leptospirosis depends on laboratory findings. The presence of leptospires may be confirmed by direct detection of the organisms or indirectly by serologic methods. Direct methods include microscopy, antigen detection, DNA detection, and culture. Microscopic methods include examination of tissue samples by dark field, histological staining, and immunohistochemical (IHC) staining methods. Visualization of leptospires by dark field microscopic examination of body fluids such as blood, urine, CSF, or dialysate fluid is insensitive and lacks specificity.<sup>61</sup> Approximately  $10^4$  leptospires/ml are necessary for one cell per field to be visible by dark field microscopy.<sup>62</sup>

The Dieterle, Steiner, and Warthin–Starry silver impregnation stains can demonstrate leptospires in tissues and body fluids; these silver stains also need special expertise in interpretation since confusion with nerve fibers, cell membrane fragments, and fibrin filaments can occur. IHC staining techniques using immunoalkaline phosphatase<sup>17,32,63</sup> or immunoperoxidase<sup>64</sup> staining methods can readily demonstrate leptospiral

antigens and intact leptospira in various tissues (Fig. 46-8). Examination of postmortem human tissues, such as kidney, liver, lymph node, and lung, by the immunoalkaline phosphatase method has proved to be a valuable tool in the investigation of leptospirosis outbreaks.<sup>32</sup>

An antigen detection assay was described,<sup>65</sup> but this assay has not been applied widely. Isolation of leptospires in culture from clinical material is a definitive diagnostic test. However, isolation of leptospires requires special media,<sup>66,67</sup> and unless there is a high index of suspicion cultures are rarely performed while the patient is bacteremic during the acute phase of the illness. Leptospires grow slowly, and cultures may not be positive until several weeks after collection. These factors combine to lower the recovery rate of leptospires and render culture almost invariably unhelpful for individual patient management.

Several polymerase chain reaction (PCR) primer pairs have been described for amplification of leptospires, but few have been shown to amplify leptospiral DNA from human or veterinary clinical material, and only two methods have been subjected to extensive clinical evaluation.<sup>68,69</sup> Both approaches have limitations: The primers described by Merien and colleagues<sup>70</sup> amplify a 331-base pair (bp) fragment of the *rrs* (16S rRNA) gene of both pathogenic and nonpathogenic leptospires, whereas the G1/G2 primers described by Gravekamp and associates<sup>71</sup> do not amplify *L. kirschneri* serovars, necessitating the use of two primer pairs for detection of all pathogenic serovars.<sup>72</sup> Using these two primer pairs, leptospiral DNA has been amplified from serum,<sup>68,69,71</sup> urine,<sup>68,69,73</sup> aqueous humor,<sup>74</sup> CSF,<sup>69,75,76</sup> and a number of tissues obtained at autopsy.<sup>77</sup> Sensitive real-time PCR assays have been developed, one targeting an 87-bp section of the 16S rRNA gene using TaqMan probe chemistry<sup>78</sup> and another targeting the *LipL32* virulence factor gene using SYBR green chemistry.<sup>79</sup>

Because of the difficulties associated with culturing leptospires and the generally low index of clinical suspicion at the time of presentation, the majority of cases of leptospirosis are diagnosed by serology. The reference standard assay is the microscopic agglutination test (MAT), in which live antigens representing different serogroups of leptospires are reacted with serum samples and then examined for agglutination by

**FIGURE 46-8** Immunostaining of leptospires in kidney. Note intact forms with typical terminal hooks, and granular forms of the bacterium. (Immunoalkaline phosphatase staining; original magnification  $\times 158$ .)

dark field microscopy.<sup>80</sup> This test requires significant expertise and resources to perform and interpret, and its use is restricted to a few reference laboratories.

A serologically confirmed case of leptospirosis is defined by a fourfold rise in MAT titer to one or more serovars between acute phase and convalescent serum specimens run in parallel. A titer of at least 1:800 in the presence of compatible symptoms is strong evidence of recent or current infection.<sup>11</sup> Suggestive evidence for recent or current infection includes a single titer of at least 1:200 obtained after the onset of symptoms.<sup>81</sup>

Cross-reactions occur between different serogroups, especially in acute phase samples.<sup>82</sup> Cross-reactivity in acute samples is due to IgM antibodies, which may persist for several years.<sup>83</sup> The MAT is a serogroup-specific assay and cannot be used to interpret reliably the identity of the infecting serovar.<sup>84</sup> Knowledge of the presumptive serogroup may be of epidemiological value in determining potential exposures to animal reservoirs.

Diagnostic application of the MAT is limited by low sensitivity when acute serum samples are tested.<sup>85</sup> Other agglutination assays that detect total immunoglobulins, such as the indirect hemagglutination assay, suffer from similarly low sensitivities on acute specimens but have high sensitivities when acute and convalescent specimens are tested.<sup>82</sup> IgM antibodies are detectable from the fifth day of illness, and commercial IgM detection assays are available in different formats.<sup>82,86–89</sup> Use of these assays as screening tests offers the potential to enhance the diagnostic capacity of many laboratories, especially those in developing countries, where most cases of leptospirosis occur.

## TREATMENT AND PROGNOSIS

Death seldom ensues in anicteric leptospirosis, and treatment with antibiotics within the first 4 days of illness will reduce the duration of illness and alleviate the symptoms. Either oral doxycycline 100 mg twice daily for 7 days or penicillin 2.4 to 3.6 million units/day in divided doses for 7 days is effective in shortening the clinical course.<sup>90,91</sup> An *in vitro* study has suggested that cefotaxime has better minimum inhibitory concentration levels than penicillin and may serve as an alternative choice. Jarisch–Herxheimer-type reactions can be seen after initiation of antibiotic treatment.<sup>92</sup> Unless there is a high index of suspicion, most cases are not confirmed at an early stage. Treatment therefore has to be early and empirical when the diagnosis is considered in the appropriate setting.

Patients presenting with severe disease are usually jaundiced or have renal insufficiency as part of Weil's disease. They should be treated with meticulous attention to electrolyte balance and rehydration to prevent anuric renal failure. If early signs of renal failure or prerenal azotemia are present, aggressive rehydration over 48 to 72 hours with intensive monitoring of the outcome may be beneficial.<sup>93</sup> If acute renal failure occurs, peritoneal dialysis, hemodialysis, or continuous venovenous hemofiltration are all effective therapies. The jaundice requires no treatment. Patients should have serial electrocardiograms performed, and if any abnormality is detected, they should be placed under continuous electrocardiographic monitoring. The treatment of arrhythmias in patients with myocarditis should be evaluated and

appropriate treatment instituted. Aggressive specific therapy for presenting signs, such as hemorrhage, hypotension, respiratory failure, or change in level of consciousness, is warranted. Controversy still exists as to whether antibiotics are of any value in the treatment of Weil's disease. From several clinical studies, it was concluded that penicillin has little effect on the clinical outcome of severe leptospirosis, except for leptospiuria.<sup>92,94,95</sup> In any controversy, patients should be given the benefit of the doubt. Intravenous penicillin or cefotaxime should therefore be given in this group of patients. It was also suggested that all patients with anicteric leptospirosis be treated irrespective of the time in the course of illness. Further studies need to be done with more clearly defined criteria for severe disease and patient exclusion to answer the question as to the efficacy of antibiotics in Weil's disease.

## PREVENTION AND CONTROL

Strategies to prevent and control leptospirosis focus mainly on reducing direct contact with infected animals and contaminated water or soil.<sup>11</sup> The risk of contact with infected animals may be reduced by the institution of appropriate sanitation measures among veterinarians, farmers, and others who handle animals. Since rodents are important natural reservoirs for leptospires, reduction of rodent populations can reduce the incidence of human leptospirosis in endemic areas. However, in places with poverty and poor sanitation, reduction of exposure to rodents may be difficult. Prevention of indirect exposure, or exposure to contaminated water or soil, is more difficult, but a common recommendation is to wear rubber boots and protective clothing and, where possible, to avoid exposure to contaminated rivers, streams, still water, and mud.

Prevention programs for domestic animals have long included leptospira vaccines.<sup>96–99</sup> Effective vaccines are available for cattle, swine, and dogs. The vaccine for cattle generally includes *L. interrogans* serovar *hardjo*; the vaccine for swine usually includes serovars *pomona*, *grippotyphosa*, *canicola*, and *icterohaemorrhagiae*; and the vaccine for dogs includes *L. interrogans* serovars *canicola* and *icterohaemorrhagiae*. Vaccinated dogs are protected against clinical leptospirosis but continue to shed live leptospires. Immunization of humans is not a common practice, but trials of human vaccines to specific serovars have been attempted successfully in mines in Japan and rice fields in Italy and Spain. Vaccine trials are under way in China, Korea, and Cuba. The major problem with vaccination of humans is that immunity is serovar specific, and it is very difficult to select all the potentially important serovars for the vaccines.<sup>100–102</sup>

To be effective, the vaccine must include the serovar(s) responsible for the majority of infections in the community. In addition, the incidence of disease should be high enough to justify immunization of people considered to be at high risk for leptospirosis.

## Trachoma

CHANDLER R. DAWSON  
JULIUS SCHACHTER

### INTRODUCTION

Trachoma is a chronic conjunctivitis that progresses to scarring of the conjunctiva, painful intumed eyelashes, and corneal scarring with blindness. Blinding trachoma is still highly endemic in many developing countries, where 84 million people have active, infectious trachoma, 7.6 million have trachomatous intumed eyelids needing corrective surgery, and 6 million are blind from the disease.<sup>1,2</sup>

The disease was once found throughout the world but has disappeared from temperate climates with industrialization and improving socioeconomic and hygienic conditions. Today, most trachoma is found in tropical and subtropical areas. It is endemic in many countries in Africa, was common in the southern Mediterranean and Middle East, and can be found in countries of South Asia, some parts of China, Australasia, and South and Central America.<sup>2</sup>

Blinding endemic trachoma of developing countries is caused by infections with *Chlamydia trachomatis* serovars A, B, Ba, or C. Eye infection caused by the sexually transmitted *C. trachomatis* serovars D through K can produce conjunctivitis resembling the early inflammatory phases of endemic trachoma, but without conjunctival scarring and blindness.

A major effort to control blinding trachoma was established by the World Health Organization (WHO) in 1997 as the "Global Elimination of Blinding Trachoma by 2020 (GET 2020)."

### AGENT

#### Biologic Characteristics

*C. trachomatis*, the causative agent of trachoma, is one of three species within the genus *Chlamydia* that are human pathogens.<sup>3</sup> *C. trachomatis* causes trachoma. It also contains serovars that cause genital tract disease and is now identified as the most common sexually transmitted bacterial pathogen (see Chapter 48). *C. psittaci* is almost ubiquitous among avian species and causes the human disease psittacosis, but it also includes other strains of mammalian origin (see Chapter 49).

*C. pneumoniae* is a human pathogen with a worldwide distribution.<sup>4</sup> It is a major cause of respiratory disease and is an etiologic candidate in cardiovascular disease.

Chlamydiae have a complex cell wall (similar to gram-negative bacteria in composition), both DNA and RNA, prokaryotic ribosomes, and metabolic enzymes that would permit independent existence, except that they lack energy-production mechanisms. Moulder<sup>5</sup> thus termed the chlamydiae to be "energy parasites" and credited their obligate intracellular parasitism to this trait.

An unusual characteristic of the obligately intracellular chlamydiae is their developmental growth cycle. The extracellular form of the organism is the elementary body, and it alone is infectious and is responsible for cell-to-cell spread and person-to-person transmission. Following attachment, the elementary body enters the host cell, apparently by a receptor-mediated endocytosis process. If the particles are viable, or do not have antibody attached, they prevent lysosomal fusion and undergo replication in the phagosome. Within 6 to 8 hours of ingestion, the elementary body is reorganized into a reticulate body (the only form that replicates). This larger, thin-walled form diverts the host cell's synthetic functions for its own metabolic purpose and proceeds to divide by binary fission. The reticulate bodies are not infectious. After 18 to 24 hours, the reticulate bodies become reorganized into elementary bodies and thus become infectious again. Subsequently, elementary bodies may disrupt and exit the host cell to infect new cells. The full cycle takes about 72 to 96 hours for the trachoma biovar. These intracytoplasmic collections of elementary bodies constitute the inclusions that may be seen in cytologic smears stained by Giemsa or immunofluorescence methods.

Although all chlamydiae share a genus-specific antigen, there is little DNA homology among *C. trachomatis*, *C. psittaci*, and *C. pneumoniae* strains.<sup>3</sup> These three species of chlamydiae are distinguished by several features. The elementary body of *C. pneumoniae* is pear-shaped with a large periplasmic space, whereas the elementary bodies of the other two species are round with little or no periplasmic space. The inclusions of *C. trachomatis* accumulate glycogen and thus stain with iodine, whereas the inclusions of *C. psittaci* and *C. pneumoniae* do not. The inclusions of *C. trachomatis* are more compact than those of *C. psittaci* and *C. pneumoniae*. A fourth difference is their response to sulfonamides: *C. trachomatis* is sensitive, but *C. psittaci* and *C. pneumoniae* are not.

*C. trachomatis* can be further subdivided into strains that cause lymphogranuloma venereum (LGV) and strains that cause oculogenital infections. They differ significantly in their biologic activity. LGV strains are more invasive and can infect many tissues in addition to epithelial cells (e.g., lymph node invasion, forming the characteristic bubo). This property permits more active cell-to-cell transmission in cell culture and the use of animal inoculation (e.g., mouse) for diagnostic purposes. The oculogenital strains, constituting the trachoma biovar, consist of at least 12 serotypes.<sup>6</sup> They are not readily invasive in tissue culture and in vivo grow only in columnar

and squamocolumnar epithelial cells (conjunctivae, respiratory tract, urethra, cervix, rectal mucosa).

Previously, it has not been possible to identify biologic properties that differentiate the serovars associated with blinding trachoma from those of the trachoma biovar associated with genital tract disease. Recently, however, two sets of genes have been identified that suggest such a differentiation. The polymorphic membrane protein gene designated *pmpH* has been shown to differ in ways that are consistent with each of these three disease-causing groups of *Chlamydia trachomatis*.<sup>7</sup> This observation suggests distinct evolutionarily divergent patterns for this gene.

More exciting, because of the functional implication, have been the findings relevant to the presence of a tryptophan synthase.<sup>8</sup> This enzyme converts indole into tryptophan. The isolates from trachoma do not have the enzyme, whereas isolates of genital tract origin do (whether they are LGV or trachoma biovars). Gamma-interferon is an important host response to chlamydial infection and is known to interfere with the completion of the chlamydial developmental cycle. Its action is thought to be due to tryptophan depletion. In vitro interferon's inhibitory effect in cell culture can be reversed by adding indole, if the chlamydiae possess a functional tryptophan synthase. This "indole rescue" was only observed with isolates of genital tract origin. This likely represents selection for a survival characteristic of the organism. The authors posit that presence of the enzyme allows for productive infection in the genital tract where normal flora may produce indole, thus allowing the chlamydiae to escape the interferon effect.

### Antigenic Composition and Diversity

Human strains of *C. trachomatis* have been classified into more than 18 serovariants (serovars) and 2 biovariants (biovars): the trachoma biovar (serovars A through K and type variants) and the LGV biovar (serovars L1 to L3).<sup>8</sup> Infections with the trachoma biovar strains are limited to columnar mucous epithelium resulting in ocular infections, inclusion conjunctivitis, and trachoma, as well as genital tract infections. Serovars A, B, Ba, and C are typically associated with endemic trachoma, whereas all the serovars have been found in the genital tract (although generally with a preponderance of serovars D and E). Virulence differences have yet to be identified that could account for this distribution of serovars. Even between the biovariants, the molecular basis of virulence differences is unknown.

All chlamydiae share a common lipopolysaccharide (LPS), which is similar in structure but less complex than LPS from gram-negative bacteria.<sup>9</sup> Significantly, the chlamydial LPS is antigenically distinct from that of most other bacteria and represents an important target for culture-independent diagnostic assays. Another essential antigenic component is the surface-exposed major outer membrane protein (MOMP).<sup>10</sup> The MOMP is antigenically complex and displays both serovar-specific antigens and antigens shared by *C. trachomatis* strains that cause human infection.<sup>11</sup> The latter antigen is also used for culture-independent detection of *C. trachomatis*. Consequently, diagnostic assays that detect LPS will identify all chlamydial species, whereas assays that detect MOMP will not identify *C. psittaci* or *C. pneumoniae*. Unlike the LPS

antigens, the MOMP antigens are targets of host immunity. This conclusion has been supported by an association of immune protection with serovar specificity and by in vitro neutralization of infectivity using anti-MOMP monoclonal antibodies.<sup>12</sup>

### EPIDEMIOLOGY

Trachoma has a worldwide distribution, and blinding trachoma is still a major public health problem in sub-Saharan Africa; in the Middle Eastern crescent; in Central, South, and East Asia; and in limited areas of the Americas, Australasia, and the Pacific islands.<sup>1,2</sup> Nonblinding trachoma is present in a much larger region of these same areas, which includes most of the drier subtropical and tropical countries. Trachoma was once prevalent and severe in many countries of Europe, North America, and Asia, but it regressed and disappeared with the rising living standards that accompanied industrialization and economic development.

Trachoma rarely occurs with the living conditions in developed countries and in many urban communities of developing countries. In persons with clinically healed trachoma, however, there may be recurrences of active disease, following treatment with topical corticosteroids, with recurrent atopic conjunctivitis, and in old age. This recurrent adult disease usually does not present a significant public health risk, however.

In communities with blinding trachoma, most children are infected by the age of 1 or 2 years, and active inflammatory trachoma is most prevalent in 2- to 5-year-olds. The prevalence of active disease then declines steadily, although some adults continue to have signs of active disease.<sup>13</sup> Thus children are the chief reservoir of ocular chlamydial infection in communities with endemic trachoma. Blinding lesions (inturned eyelids and corneal scarring) are the outcome of earlier severe or moderate-intensity inflammatory disease. These blinding sequelae are generally observed in adults but may occur in childhood as the result of very severe inflammatory disease.

### Risk Factors

Trachoma is associated with poverty. Economic development appears to eliminate or reduce the severity of the disease. Transmission of the disease is by direct or indirect contact with infected material (e.g., hands, clothing, towels) and by flies. Among the environmental features of greatest importance are the presence of young children in the household, crowding, and the unavailability of safe water and household latrines.<sup>14,15</sup> The behavioral risk factors associated with the severity of trachoma are primarily the lack of facewashing of young children and the lack of latrines in households.

In many endemic areas, the open disposal of human and animal wastes contributes to an increase in the fly population. The flies that cluster on children's eyes to feed on ocular discharges can transfer these discharges to the eyes of other children in the same family within 15 to 30 minutes.<sup>16-18</sup> Children with endemic trachoma also harbor *C. trachomatis* in the upper respiratory and gastrointestinal tracts.<sup>19</sup> Thus, transmission may also occur by aerosol droplet spread and fecal contamination of fomites, as well as by flies.

**FIGURE 47-1** Active infectious trachoma. The presence of lymphoid follicles (white, avascular spots) in a bed of punctate dilated capillaries and diffuse infiltration (papillary infiltration) on the conjunctiva of the upper eyelid indicates active, presumably infectious, trachoma in this Tunisian child. (The numbered label was used to identify the child in a therapy trial.)

## DISEASE

In communities with endemic trachoma, the disease often has inapparent or gradual onset. Initially, trachoma presents as conjunctivitis characterized by the formation of lymphoid follicles in the subconjunctival tissue and inflammatory infiltration (papillary hypertrophy) of the conjunctiva (Fig. 47-1). In children under 2 years of age, the papillary reaction with inflammatory thickening of the conjunctiva may be the predominant sign, and follicles may not be a prominent sign. The disease involves the entire conjunctiva, but its effects are most noticeable on the upper tarsus, which has been selected as a diagnostically critical area for examination to represent the degree of trachomatous inflammation and scarring.<sup>20</sup>

As chronic trachoma progresses, it causes scarring of the conjunctiva (Fig. 47-2), with fine linear and small stellate

**FIGURE 47-2** Trachoma scarring and Herbert's pits in a 6-year-old Tunisian child. The scars are a network of white lines on the conjunctiva of the upper eyelid. Between the scars there are still a few follicles and a diffuse inflammatory infiltrate. The lid margin has been pulled inward so the orifices of the meibomian glands appear to open on the conjunctival surface. Herbert's pits are seen here as circular round depressions at the conjunctival-corneal border. They are found only with trachoma.

**FIGURE 47-3** Trachomatous trichiasis. Conjunctival scarring acquired in childhood has caused gradual contraction of the lid margins producing inturned lashes (trichiasis and entropion) from the lower lid, which abrade the cornea.

scars in milder cases, or broad confluent or synechial scars in severe cases. With severe scarring, there is distortion of the lids, particularly of the upper tarsus, to produce inturned eyelashes (Fig. 47-3). The disease also can destroy the mucus-secreting conjunctival goblet cells and injure the lacrimal glands and tear ducts. Thus, constant corneal abrasion by the inturned eyelashes and deficient tear secretion can lead to corneal ulceration followed by opacification and visual loss. The deep trachomatous scarring in the upper tarsus and fornix may also produce defects in lid closure with exposure of the cornea, which also predisposes to traumatic and infectious damage to the cornea (Fig. 47-4).

During its inflammatory infectious phases, trachoma produces lesions of the cornea ranging from fine punctate defects in the epithelium (epithelial keratitis) to infiltrates of the superficial stromal connective tissue and superficial neovascularization (vascular pannus). A unique characteristic of trachoma is the formation of lymphoid follicles at the conjunctival-corneal junction (limbus), which on resolution

**FIGURE 47-4** Corneal scarring and trichiasis in trachoma. The constant abrasion by eyelashes and the altered tear film have produced corneal damage leading to opacification in this 48-year-old Tunisian woman.

leave characteristic depressions at the limbus called Herbert's peripheral pits (see Fig. 47-2).

The degree of conjunctival scarring is directly proportional to the intensity and duration of inflammation.<sup>21</sup> Very severe scarring occurs in children as young as 4 or 5 years of age. Inturned eyelids are uncommon at this age, however, and tend to occur in late adolescence and early adult life, long after the active inflammatory disease has subsided. This late onset of inturned lids in adults may be due to repeated episodes of infection with the development of more scarring and the gradual contraction of the lid margin.

The older MacCallan classification is rarely used now, and there are two related systems recommended by the World Health Organization (WHO) to describe the clinical findings.<sup>20,22</sup> For this clinical evaluation, signs involving the upper tarsal conjunctiva are used as a convenient index of the disease process. These conjunctival signs include lymphoid follicles, diffuse infiltration and papillary hypertrophy, conjunctival scarring, inturned eyelashes, and corneal opacity.

The detailed WHO descriptive system emphasizes the grading of the intensity of inflammatory disease on the basis of tarsal follicles and of diffuse inflammation and papillary hypertrophy. Cicatricial signs include conjunctival scarring, inturned eyelashes, and corneal opacity.<sup>20</sup> This detailed description has been useful for clinical research in field studies.

A simplified description was introduced in 1987 by the WHO for use by primary health-care workers (Box 47-1).<sup>22</sup> This simplified system was developed for use by nonspecialist health workers in developing countries, using a handlight and loupe for examination. A specific series of interventions is linked to the clinical findings.

To identify the presence or absence of trachoma in a community, individual cases must have at least two of the following signs: (1) follicles in the upper tarsal conjunctiva, (2) limbal follicles or their sequelae, Herbert's pits (see Fig. 47-2), (3) typical conjunctival scarring, and (4) vascular pannus more extensive at the superior limbus.<sup>20</sup> Communities with blinding trachoma have a high prevalence of older persons with severe

visual loss caused by corneal opacity and a substantial prevalence of potentially disabling trachomatous lesions, specifically inturned eyelashes.<sup>13</sup> These irreversible changes are the long-term outcome of prolonged or recurrent inflammatory disease of moderate or severe intensity. Communities with nonblinding trachoma may have a low incidence of potentially blinding lesions and little if any visual loss from trachoma.

In communities with blinding trachoma, chlamydial infection is always present, but other ocular microbial pathogens appear to contribute significantly to the intensity of trachoma and to the lesions that impair vision.

## PATHOGENESIS AND IMMUNITY

The host response of the human conjunctiva in trachoma is characterized both clinically and histologically by the presence of lymphoid follicles with germinal centers.<sup>23-25</sup> In the early stages of trachoma, the epithelial and subepithelial tissues are infiltrated with lymphocytes and polymorphonuclear leukocytes. Where the conjunctiva is bound down over the tarsal plate, the epithelium is elevated by infiltrating inflammatory cells to form papillae with vascular tufts and folds of epithelium between the elevations.

Early in the disease, collections of lymphocytes appear in the submucosa just beneath the epithelium or deeper within the connective tissue. These early follicles do not have germinal centers and appear to consist mostly of small lymphocytes. As the disease progresses, the collections of lymphocytes develop into lymphoid germinal centers, with an outside layer of small, dense lymphocytes and an inner center of lighter-staining cells with more cytoplasm. Unlike central lymph nodes, these lymphoid follicles are displaced toward the surface. The lymphocytes of the subepithelial follicles appear to be infiltrating the overlying conjunctival epithelium, which is flattened and loosened over the follicle itself, allowing ready access of foreign material into the follicle. Lymphoid follicles in the conjunctiva can also occur deeper in the connective tissue and are not necessarily adjacent to the conjunctival epithelium. Between follicles, the epithelium and submucosal layers are diffusely infiltrated with lymphocytes and some polymorphonuclear cells.

In more advanced stages of trachoma, the follicle itself becomes necrotic, and connective tissue forms in and around the follicles, producing scarring. The formation of Herbert's pits by follicles at the corneoscleral junction (limbus) is evidence that the follicle (during its formation in this confined space) can erode the connective tissue without causing any overt ulceration or connective tissue reaction with scarring.

Macrophages are frequently found in the epithelium and in the follicles themselves. Plasma cells appear to be distributed throughout the conjunctiva. Between the follicles, there is marked lymphocytic infiltration. In addition, the capillaries are dilated, and the whole conjunctival layer is thickened by the cellular infiltration with the formation of papillary villi. As scarring takes place, islands of epithelium between the elevated papillae may become trapped and form epithelial-lined cysts, which fill with desquamated debris to form yellow structures, clinically identified as "post-trachomatous degeneration." Progressive scarring produces inward deformation of the lid margins with inturned eyelashes (trichiasis and entropion),

### Box 47-1 Simplified Description of Trachoma for Primary Eye Care

Trachoma follicles	Five or more lymphoid follicles on the central area of the upper tarsal conjunctiva
Trachomatous inflammation	Diffuse inflammation of the tarsal conjunctiva that obscures more inflammation than half of the normal deep tarsal vessels
Trachomatous scarring	Any characteristic scarring of the tarsal conjunctiva
Trichiasis or entropion	At least one or more deviated lashes touching the eyeball
Corneal opacity	Easily visible corneal opacity or scarring over the pupil

From Thylefors B, Dawson CR, Jones BR, et al: A simple system for the assessment of trachoma and its complications. *Bull World Health Org* 65:477, 1987.

which constantly abrade the cornea to produce corneal scarring and blindness.<sup>23</sup>

## DIAGNOSIS

The laboratory methods for diagnosis of *C. trachomatis* in patients with trachoma are essentially the same procedures that have been used to diagnose chlamydial genital tract infections (see Chapter 48). There have been many evaluations of the sensitivity and specificity of these tests for diagnosis of sexually transmitted diseases. It is far more difficult to perform rigorous evaluations in trachoma-endemic areas because of the difficulties in maintaining cold chains and establishing appropriate “gold standards” for comparison. In developing countries, the time-honored Giemsa stain may still be of use in detecting chlamydial inclusions in conjunctival scrapings from some cases of severe active trachoma.<sup>26</sup> Antigen detection methods, such as direct fluorescent antibody (DFA) and enzyme immunoassay (EIA) are also of some use, but they are less sensitive than the newer amplified DNA tests.<sup>27</sup> These are probably the tests of choice for field studies because they do not require maintenance of a cold chain and the specimens can be sent back to reference laboratories or be tested locally.

*C. trachomatis* can be identified in cytologic scrapings or in tissue specimens by recognition of characteristic intracytoplasmic inclusions.<sup>26</sup> Such identification in conjunctival epithelial cells, and less frequently in cervical epithelial cells, constituted the only technique available at the time when trachoma and oculogenital diseases were first recognized, at the turn of the 20th century, until the organism was isolated in embryonated eggs in 1957 by Tang and associates in Beijing.<sup>28</sup>

This diagnostic approach has been supplanted by the use of cell culture isolation methods and by the use of modern nonculture diagnostic tests that detect chlamydial antigens or genes. For many years, the most sensitive method for identification of *C. trachomatis* infection of the genital tract was isolation in cell culture. Direct methods of detection of chlamydial DNA (DNA probes) have not been more sensitive than EIA procedures. However, the introduction of amplified DNA technology, such as the polymerase chain reaction (PCR) or ligase chain reaction (LCR), in the mid-1990s revolutionized chlamydial diagnostics.<sup>29,30</sup> These tests are highly specific and are more sensitive than any other diagnostic tests, including culture. The broad-based use of LCR or PCR has greatly improved the management of genital infections by *C. trachomatis*, but has not yet been applied in trachoma control.

## Isolation

The method of choice for recovery of *C. trachomatis* is by cell culture using McCoy, HeLa-229, BHK-21, or L-929 cells. A necessary step in cell cultivation of *C. trachomatis* strains other than LGV is centrifugation of the inoculum onto the cells. In addition, the cells are treated to enhance infection; Gordon and colleagues, who developed the modern cell culture technique, used irradiation of McCoy cells.<sup>31</sup> Cycloheximide has been substituted for irradiation, and cycloheximide-treated McCoy cells are the most widely used cultivation method at present.<sup>32</sup> Specimen material is inoculated into

individual vials with cell sheets on coverslips within them or into wells of microtiter plates that have been implanted with cells. They can be examined at 48 to 96 hours after inoculation. Intracytoplasmic inclusions can be recognized by iodine, Giemsa, or more commonly by fluorescent antibody (FA) staining. Iodine stain only identifies *C. trachomatis* strains. FA stains are more sensitive and can be species-specific (to MOMP) or genus-specific (to LPS).

## Antigen and Nucleic Acid Probes

In recent years, other nonculture diagnostic methods have been evaluated and widely used, including DFA, EIA, and DNA probe methods. There are a number of DFA kits commercially available. Although they differ primarily in their specificity and in their ease of laboratory use, the general principle is the same. A cytologic smear is fixed (at which stage it can be stored), stained with a fluorescein-conjugated monoclonal antibody, and examined by ultraviolet microscopy. Elementary bodies are recognized as small apple-green dots. When the test is performed by experienced persons, the sensitivity can be as high as 90%, but is more often 70% to 80%. The specificity is usually 98% or greater. Thus, it is an excellent screening test for high-risk populations, but less useful in low-prevalence populations.<sup>27,33</sup>

The EIA class of tests is designed for immunochemical detection of dissolved antigenic components. The tests have been designed with the use of plastic to absorb chlamydial LPS or with antigen capture in a sandwich format.<sup>34</sup>

Both DFA and EIA are technologically easier and are less difficult to transport than cell culture. However, they have lower sensitivity and specificity. The DFA has the advantage of a verifiable sample quality, rapidity (as little as 30 minutes), and no restriction as to specimen site. EIA requires less training and experience because its indicator is more objective; it is more suitable for batch processing, and it can be automated.

Direct nucleic acid probes are commercially available. They are less sensitive than culture, although they are highly specific.<sup>34</sup> In contrast, the amplified DNA technology, exemplified by LCR and PCR, is far more sensitive than cell culture and is extremely specific.<sup>29,30,35</sup> The chlamydial genes can be detected in epithelial cell specimens and in male and female urine samples.<sup>36,37</sup> Although noninvasive sampling (urine) is important for diagnosing sexually transmitted diseases, conjunctival swabs are still needed to collect specimens for trachoma.

Except for the DFA smears, specimens for trachoma should be kept at 5°C (i.e., on ice) for transport from the field. As with antigen detection methods, there is the drawback that no propagated organism is available for further identification (e.g., serologic markers, or testing for antibiotic sensitivity). Also, direct detection methods may be more expensive than culture.

## Serologic and Immunologic Diagnostic Methods

Although a variety of serologic methods have been used in the past to detect antibodies, the indirect immunofluorescence method, first developed by Bernkopf and then by McComb and Nichols, has been simplified and standardized in an indirect microimmunofluorescence (MIF) test by Wang and associates.<sup>38</sup> At present, this is the most commonly used

test for evaluation of host response to trachoma or to oculogenital *C. trachomatis* agents. For LGV, the complement fixation (CF) test can be used, although the MIF test remains more sensitive and specific. The MIF test employs yolk sac–grown or cell culture–grown *C. trachomatis* of all known immunotypes as antigen. Antigen dots are placed on a slide in a specific pattern. They are attached to the slide in a diluted yolk sac suspension. Serial dilutions of serum, tears, or local secretions are applied, followed by fluorescein-conjugated antihuman globulin. An obvious advantage of the test is that the conjugate may be prepared against any immunoglobulin class, thus permitting titration of IgG-, IgM-, or IgA-specific antibody. A counterstain is added to the conjugate to permit clearer identification of specific fluorescence in the dots to which antibody-containing serum has been applied. If differentiation among antibodies to specific immunotypes is sought, the antigens can be evaluated separately. For many purposes, antigen pools can be used.

A CF test is available to measure host response to any chlamydial infection.<sup>39</sup> It is still the most commonly used test for psittacosis and LGV, but it is too insensitive for trachoma or oculogenital infections. Usually, the antigen for the CF is obtained from a yolk sac–grown LGV strain and is prepared by boiling and treatment with phenol.

## TREATMENT AND CONTROL

WHO initiated a major effort to control blinding trachoma in 1997 as the “Global Elimination of Blinding Trachoma by 2020 (GET 2020).”<sup>2</sup> A nongovernmental organization, the International Trachoma Initiative (ITI) was established in 2001 to distribute azithromycin donated by Pfizer Inc. for trachoma control. The ITI assists Ministries of Health in affected countries to develop systematic national trachoma control programs.

In trachoma-endemic regions, the goal of trachoma intervention programs is the elimination of trachoma as a blinding disease. The new programs are based on four components, the SAFE strategy: surgery to correct turned eyelids; antibiotics to eliminate the reservoir of chlamydial infection in the community and to reduce inflammation in individuals; promotion of personal hygiene, with emphasis on facial cleanliness in young children; and environmental changes to reduce transmission of trachoma through the elimination of human fecal material and provision of pure water supplies.<sup>40</sup>

### Surgery

The surgical correction of intumed eyelids (trichiasis) from trachoma is carried out with tarsal rotation procedures.<sup>41</sup> In many programs, these procedures are done by trained nurses or general physicians, less frequently by ophthalmologists. Recurrent trichiasis after surgery has been observed regularly, for example, 11% after 1 year in Vietnam.<sup>42</sup> A comparison of surgical cases done by ophthalmologists or by trained eye care workers in Ethiopia showed no difference in the rates of recurrence at 6 months (14.6%) in the two groups.<sup>43</sup>

For patients blind from trachomatous corneal scarring, corneal transplant surgery has a poor outcome. The reduced flow of tears, loss of mucus from goblet cell destruction, exposure by distorted lids, and inadequate follow-up care all contribute to graft failure in such patients.

## Antibiotics

The objectives of antibiotic treatment are to reduce the pool of chlamydial infection in the community and the severity of active trachoma, and thus of the risk of blindness, in individual cases. Sulfonamides, tetracyclines, erythromycin, other macrolides and azalides, and rifampin are effective against trachoma. Most control programs utilized topical tetracycline ointment from the 1950s to the mid-1990s. Antibiotic treatment in endemic communities (active trachoma in more than 20% of children) has been based on the supervised application of antibiotic to all persons in a community (“mass therapy”).<sup>20</sup>

The advent of oral azithromycin has led to a renewed interest in trachoma control because it is effective with one to three doses and can be taken by children as young as 6 months old.<sup>44</sup> The compliance is very high with a single dose, and the drug is well tolerated. The new recommendation for this community treatment is azithromycin, given as a single dose (20 mg/kg body weight for children, or 1 g for adults; height can be used as a surrogate for weight in children).<sup>40</sup> Because Pfizer Inc. has donated oral azithromycin for trachoma control (135 million doses committed), there is no cost of this antibiotic to programs involved in trachoma control, but there are still substantial costs for distributing it to large populations.

Initial case control studies showed that oral azithromycin was as effective or better than topical oxytetracycline ointment.<sup>44–46</sup> A subsequent trial of village-wide oral azithromycin (1 dose weekly for 3 weeks) compared to oxytetracycline ointment (1 dose daily for 42 days) in Egypt, Tanzania, and Gambia showed a substantial reduction of chlamydial infection by both treatments, but only a modest effect on clinically active trachoma.<sup>47</sup> The new goal of antimicrobial treatment is the elimination of chlamydial eye infection and thus of infectious trachoma. Elimination of trachoma in one village in Tanzania was achieved by an initial azithromycin dose (94% compliance) and topical tetracycline to active cases for 18 months.<sup>48</sup> In practice, mass treatment is carried out in communities or regions with 10% or more active trachoma in children. It is apparent that in most of these areas about 5% of the children have trachoma-like follicular conjunctivitis that is not caused by chlamydial infection.

The evaluation of antibiotic treatment has been based on the clinical diagnosis of active trachoma. After treatment, however, clinical trachoma activity is no longer an adequate surrogate for chlamydial eye infection, because the clinical signs of disease persist after the infection has resolved.<sup>49</sup> To determine the need for further rounds of mass treatment, it will be necessary to test for chlamydial eye infection, preferably by one of the nucleic acid amplification tests.

## Face Washing and Hygiene

Personal hygiene intervention is based on studies indicating that failure to wash the faces of young children is a significant risk factor for trachoma.<sup>15</sup> Face washing has been incorporated into studies of antibiotic treatment.<sup>50</sup>

## Environment

Environmental controls include the provision of latrines to reduce fly density and provision of adequate water supplies by building wells or distribution systems.<sup>14–16</sup> These activities

are important for community development; they are capital intensive and do not have an immediate effect on infectious trachoma.<sup>51</sup>

# Chlamydia trachomatis

## Infections of the Genital Tract (Oculogenital Infections and Lymphogranuloma Venereum)

RONALD C. BALLARD  
JOHN R. PAPP

### INTRODUCTION

*Chlamydia trachomatis* is primarily a human pathogen associated with medically important oculogenital infections. They are classified under the order Chlamydiales and family Chlamydiaceae. A proposal to separate members of the family Chlamydiaceae into two genera, *Chlamydia* and *Chlamydophila*,<sup>1</sup> has not been widely accepted by many workers in the field.<sup>2</sup> This reclassification would largely affect *C. pneumoniae*, which causes respiratory infections in man, and *C. psittaci*, which causes a variety of infections relevant to veterinary medicine, some of which are known zoonotic agents. There have been no proposed changes to the taxonomic classification of *C. trachomatis* associated with human infections. This chapter deals exclusively with those infections of the genital tract caused by *C. trachomatis*.

Diseases caused by *C. trachomatis* have been recognized since ancient times. Trachoma, the blinding eye disease, which is spread from eye to eye, was known in China in the 27th century BC, while its complications were described in Egypt in the Ebers papyrus as early as the 19th century BC (see Chapter 47).<sup>3</sup> Although the communicable nature of the disease was obvious to early workers, the etiologic agent was not demonstrated until 1907 when Halberstaedter and Prowazek<sup>4</sup> succeeded in infecting orangutans with material obtained from the eyes of trachoma patients. They described intracytoplasmic inclusion bodies

in conjunctival epithelial cells from infected animals and maintained that the small granules they saw within the inclusions represented the etiologic agent.<sup>4</sup> They later demonstrated similar inclusion bodies in epithelial cells obtained from trachoma patients. Similar inclusion bodies were subsequently found in cases of nongonococcal ophthalmia neonatorum and in the cervix of the mother and the urethra of the father of a baby who presented with an eye infection, and in urethral scrapings from a number of men with nongonococcal urethritis (NGU).<sup>5,6</sup>

Meanwhile, an infection of the inguinal lymph nodes (climatic bubo), frequently seen in the tropics, was first recognized as a sexually transmitted disease (STD) by Rost in 1912,<sup>7</sup> while a similar disease, lymphogranuloma inguinale, had been well documented in more temperate climates.<sup>8</sup> Subsequently, these two diseases were found to be identical, a situation that had long been suspected on both clinical and pathologic grounds.

In many respects, investigations to determine the cause of the disease now called lymphogranuloma venereum (LGV) mirror those previously described for trachoma and other chlamydial infections of the genital tract. Thus, in the early 1920s, both Gamna<sup>9</sup> and Favre<sup>10</sup> described intracytoplasmic inclusion bodies in material obtained from patients with LGV, and Gamna also found them in guinea pigs previously inoculated with pus obtained from human cases.<sup>11</sup> In 1930, Hellerstrom and Wassen<sup>12</sup> succeeded in transmitting the infection to monkeys by intracerebral inoculation, which resulted in the development of meningoencephalitis. Soon afterward, mice were infected by the same route, and lesions similar to those seen in humans were produced in monkeys and marmosets.<sup>13</sup>

A close relationship between these organisms and the causative agent of psittacosis was suggested in 1942 when sera from patients with trachoma or inclusion conjunctivitis were found to fix complement in the presence of LGV and psittacosis antigen.<sup>14</sup> These organisms were initially grouped together as the PLT (psittacosis-lymphogranuloma-trachoma) group of atypical “viruses” and later as chlamydial organisms.

### AGENT

#### Developmental Cycle

Chlamydiae are obligate intracellular bacteria with a unique biphasic life cycle (Fig. 48-1). The cycle is initiated by the attachment of an infectious elementary body to the surface of a susceptible cell. The mechanism by which chlamydiae attach to the host cell has not been fully elucidated, though electrostatic and receptor interactions have been postulated.<sup>15,16</sup> Once attached, the metabolically inactive elementary body (approximate size: 350 nm in diameter) enters the cell by phagocytosis, but the resulting phagocytic vacuole does not fuse with primary lysosomes. The prevention of lysosomal fusion is thought to be mediated by chlamydial surface antigens and dependent on the presence of living elementary bodies, since heat-killed or antibody-treated organisms are rapidly sequestered into phagolysosomes.<sup>17</sup> While in the phagocytic vacuole, the elementary body remains intact and undergoes reorganization to form, within 8 hours, what is known as the initial or reticulate body. This is a much larger (800–1000 nm in diameter) metabolically active particle that is unable to survive outside the host cell, but can replicate by binary fission to produce

**FIGURE 48-1** Schematic representation of the chlamydial developmental cycle. 0 hour: ingestion; 8 hours: reorganization into reticulate body; 16 to 24 hours: multiplication of reticulate bodies; 32 to 48 hours: multiplication and reorganization into elementary bodies; 72 hours: release of elementary bodies. N, cell nucleus.

further reticulate bodies. After approximately 20 hours, the inclusion, which has formed in the cytoplasm of the host cell, contains numerous reticulate bodies. Thereafter, reorganization of these particles to form elementary bodies occurs on a 1:1 basis. By 40 hours post infection, the inclusion contains large numbers of mature elementary bodies and a smaller number of reticulate bodies that are continuing to undergo division and reorganization. An increase in chlamydial infectivity associated with further production of elementary bodies continues until 48 to 72 hours post infection, when lysis of the host cell takes place and liberation of the contents of the mature inclusion occurs. The chlamydial development cycle thus takes approximately 2 to 3 days to complete. However, there is some variation as LGV strains generally have shorter development cycles than *C. trachomatis* strains associated with ocular and genital infections.

**Subtypes of *Chlamydia trachomatis***

Chlamydiae are antigenically complex, possessing antigens that demonstrate specificity at the genus, species, and subspecies levels. Antigenic cross-reactivity, as measured by the indirect microimmunofluorescence test,<sup>18</sup> has been used to classify isolates of *C. trachomatis* into 15 serovars (Table 48-1). The serovars are usually, but not exclusively, associated with distinct chlamydial infections; thus serovars A through C have generally been associated with hyperendemic trachoma, serovars D through K with oculogenital infections, while the L serovars have been associated with LGV.<sup>19</sup> These serovar-specific epitopes reside largely within two domains in the major outer membrane protein (MOMP) of the organism,<sup>20</sup> whereas the immunodominant genus-specific epitope is associated with the heat-stable lipopolysaccharide.

**Table 48-1** Human Diseases Caused by Chlamydiae

Species	Biovars	Disease
<i>C. trachomatis</i>	A, B, Ba, C D-K	Hyperendemic blinding trachoma Acute urethritis, cervicitis Adult and neonatal conjunctivitis Salpingitis, proctitis, epididymitis, Reiter's disease Neonatal pneumonia
	L <sub>1</sub> , L <sub>2</sub> , + L <sub>3</sub>	Lymphogranuloma venereum Proctocolitis
<i>C. psittaci</i>	Many, uncharacterized	Pneumonia, endocarditis, abortion
<i>C. pneumoniae</i>	? Only one	Community-acquired pneumonia Bronchitis ? Circulatory disease

As expected, polymorphisms within the gene that encodes the MOMP, *ompA*, parallel the designations assigned by seovar analysis.<sup>21</sup> Genotype determination has proven to be useful in epidemiologic studies since it can be accomplished directly from clinical specimens without the need to isolate the organism.<sup>22</sup> The *ompA* polymorphisms provide a higher level of discrimination by identifying variants within the parent genotype. These variants may be useful in determining sexual networks and assessing the impact on immune selection.

## DISEASE

### Oculogenital Infections

In terms of their clinical manifestations, genital infections caused by serovars D through K of *C. trachomatis* closely parallel those caused by *Neisseria gonorrhoeae*, since they share the same cell target, namely, columnar epithelial cells. However, generally, infections caused by *C. trachomatis* tend to produce milder symptoms than those caused by *N. gonorrhoeae*, probably because *C. trachomatis* infection elicits a less severe acute inflammatory reaction.

### Infections of the Genital Tract in Men

Chlamydial infection of the urethra results in the development of NGU. *C. trachomatis* is the causative agent in approximately 50% of cases of NGU, while other possible causes include *Mycoplasma genitalium* and *Ureaplasma urealyticum*. Clinically, chlamydia-positive and chlamydia-negative NGU cannot be differentiated on the basis of signs or symptoms. The incubation period of NGU (including chlamydial urethritis) is longer than that of gonorrhoea, varying from 1 to 3 weeks in the majority of cases, and the onset of symptoms of NGU is more insidious. These symptoms include dysuria, appearance of a clear or white urethral discharge, and occasionally frequency of micturition. Many patients may be asymptomatic or minimally symptomatic, which results in prolonged periods when they may be infectious to their sexual partner. Despite these mild manifestations, it is often difficult to differentiate between gonococcal and chlamydial infections on clinical grounds alone and, indeed, the two infections may coexist in up to 30% of cases of acute gonococcal urethritis.<sup>23</sup> *C. trachomatis* is also a frequent cause of postgonococcal urethritis (PGU), which follows treatment (normally single dose) of mixed gonococcal-chlamydial infections with an antibiotic that is active against *N. gonorrhoeae* but not against *C. trachomatis*. In industrialized societies, PGU is usually symptomatic, but in the developing world, the majority of cases are apparently either asymptomatic or minimally symptomatic.<sup>24</sup>

*C. trachomatis*, along with *N. gonorrhoeae*, has emerged as a major cause of acute epididymitis in sexually active young men. Chlamydiae were initially isolated from epididymal aspirates obtained from patients in the United States who were all under 35 years of age and who presented with concomitant urethritis. This contrasted with the findings in older men who did not present with urethritis and from whom only gram-negative bacilli could be isolated.<sup>25</sup> Studies of the role of *C. trachomatis* in the etiology of acute epididymitis in mine-workers in South Africa have also indicated that chlamydial infection is probably more important than gonococcal infection

as a cause of this complication in developing societies.<sup>24</sup> In contrast, a role for *C. trachomatis* in the etiology of chronic abacterial prostatitis remains speculative despite the proven link between *N. gonorrhoeae* and acute bacterial prostatitis.<sup>26</sup>

### Infections of the Genital Tract in Women

The endocervix is the most common site of infection with *C. trachomatis* in women. In many cases, the infection may be completely asymptomatic. However, those with symptoms may complain of vaginal discharge, dysuria, or lower abdominal pain. On examination, the cervix may appear normal or may be severely eroded with follicular hypertrophy and an associated mucopurulent endocervical discharge. Likewise, chlamydial infection of the urethra in women may either be asymptomatic or associated with urethral symptoms such as dysuria and frequency. *C. trachomatis* has been implicated in over 60% of cases of the so-called acute urethral syndrome in women. The infection is characterized by the presence of urethral symptoms together with a sterile pyuria.<sup>27</sup>

Ascending spread of *C. trachomatis* from the endocervical canal to the endometrium, fallopian tubes, and peritoneal cavity is the most serious complication of both asymptomatic and symptomatic chlamydial infection in women. The organism is capable of inducing a plasma cell endometritis, acute and chronic salpingitis, and full-blown peritonitis with associated perihepatitis (Fitz-Hugh–Curtis syndrome) and periappendicitis. Infected pregnant women are at risk of developing late postpartum endometritis. Resolution of these upper genital tract infections may result in chronic pelvic pain, tubal infertility, or ectopic pregnancy. However, a body of evidence has accumulated that the majority of cases of chlamydial salpingitis are symptom-free and that these cases of so-called “silent PID” may contribute significantly to tubal infertility.<sup>28</sup>

### Other Infections in Adults

*C. trachomatis* may cause a proctitis and pharyngitis in both men and women, and accidental inoculation of the eye may result in the development of adult inclusion conjunctivitis. *C. trachomatis* may be associated with 50% of cases of sexually acquired reactive arthritis (SARA) by acting as a trigger to precipitate the disease in genetically predisposed (HLA-B27-positive) persons.<sup>29</sup> In a few cases, the urethritis and arthritis may be accompanied by both the conjunctivitis and the mucocutaneous lesions classically associated with Reiter's disease.

### Neonatal Chlamydial Infections

Neonatal inclusion conjunctivitis has long been recognized as the result of an infection transmitted from mothers to their babies during passage through the birth canal. With the advent of sensitive tissue culture techniques, it became apparent that some babies delivered vaginally through an infected cervix developed a mucopurulent conjunctivitis. The onset of the disease is generally insidious, following an incubation period of 1 to 3 weeks. Hyperemia, chemosis, and a discharge that becomes progressively purulent are the most prominent features of the infection. However, lymphoid follicles, which are characteristically found in adult chlamydial infections of the eye, are notably absent unless the infection persists for more

than a month. In the majority of cases, spontaneous cure occurs without scar formation or the appearance of any sight-threatening sequelae.

*C. trachomatis* is also recognized as a significant cause of neonatal pneumonia.<sup>30</sup> Following an incubation period of 2 weeks to 3 months, infants with *C. trachomatis* pneumonia develop rhinitis which is often accompanied by conjunctivitis. They are usually afebrile, tachypneic, occasionally apneic, and develop a staccato cough. Chest radiography reveals hyper-inflation with diffuse interstitial infiltrates. Laboratory investigations frequently reveal eosinophilia and hypergammaglobulinemia, particularly associated with an elevation of immunoglobulin M (IgM) levels. In the majority of cases, the infection is mild and either resolves spontaneously or after a short course of anti-chlamydial therapy. Unfortunately, a minority of infants requires intensive therapy, and their subsequent ability to withstand respiratory infections may be impaired.<sup>31</sup> Neonatal chlamydial infections of the middle ear, vagina, and rectum have also been documented.<sup>32</sup>

### Lymphogranuloma Venereum

The causative agent of LGV is usually a strain of *C. trachomatis*, although a *C. psittaci* strain has been isolated from one case clinically resembling LGV. As a general rule, the organisms causing LGV (L serovars) are more invasive than those that cause trachoma and other genital tract infections, and this property has been used to differentiate between chlamydial isolates in cell culture.<sup>33</sup>

The disease has a worldwide distribution, but is most prevalent in tropical and subtropical countries. The rapid growth of international travel has also resulted in an increasing number of cases being reported from Europe, and many cases were imported into the United States by servicemen returning from Southeast Asia in the 1970s. More recently, outbreaks of LGV proctocolitis have been documented among men who have sex with men (MSM) in European countries that traditionally had few reports of disease.<sup>34</sup>

Classically, LGV presents as a transient, herpetiform primary lesion of the external genitalia (Fig. 48-2), but in many cases the lesion may pass unnoticed or manifest as an acute non-gonococcal urethritis in men or be completely asymptomatic in women as a result of primary infection of the cervix. Most cases seek medical attention when the regional lymphatics become infected. In men, swelling of the inguinal and femoral lymph nodes often results in the formation of suppurating buboes on either side of the inguinal ligament (the groove sign; Fig. 48-3). In women, the perirectal and deep pelvic lymph nodes may become involved if the primary lesion is found on the cervix, and the patient may present with symptoms consistent with severe pelvic inflammatory disease.

MSM may present with a severe ulcerative proctocolitis with a blood-stained rectal discharge.<sup>35</sup> In common with women, who also present with such lesions, failure to treat the disease at this stage may result in the formation of perirectal abscesses, rectal strictures, and fistulas. Apart from these complications, which arise as a result of acute inflammatory changes, chronic manifestations of the disease may result in blockage of the lymphatics draining the genitalia or rectum, causing edema. When this lymphatic edema is severe, it is termed *elephantiasis*.<sup>36</sup>

**FIGURE 48-2** Primary ulceration of lymphogranuloma venereum in the coronal sulcus.

### EPIDEMIOLOGY IN DEVELOPING COUNTRIES

Chlamydial infections of the genital tract have a worldwide distribution and usually constitute the most common bacterial sexually transmitted infection in both industrialized and developing countries. Genital chlamydial infections share those behavioral determinants that are responsible for the spread of other sexually transmitted infections—factors that are frequently more evident in many developing country settings. The ability of *C. trachomatis* to elicit a relatively mild inflammatory reaction has resulted in the majority of infections in both men and women being either asymptomatic or minimally symptomatic.

**FIGURE 48-3** Left inguinal lymphadenopathy in a patient with lymphogranuloma venereum. Note involvement of both the inguinal and femoral glands and the formation of the classic "groove sign."

In many developing countries, failure of individuals to recognize the significance of mild symptoms, together with a lack of specific diagnostic facilities, has resulted in the relative importance of these infections remaining unrecognized, particularly as a cause of morbidity among women and neonates.

While sexually transmitted genital ulcer disease has been recognized as a major cofactor in the heterosexual transmission of HIV infection in developing countries, an increase in number of CD4+ inflammatory cells in genital exudates elicited by mucosal chlamydial infection has also been considered to enhance human immunodeficiency virus (HIV) susceptibility and transmissibility at the individual level and, overall, to increase community vulnerability to HIV in those populations where chlamydial infection of the genital tract is endemic.

## **PATHOGENESIS AND IMMUNITY**

Chlamydiae have little if any intrinsic toxicity and thus disease is primarily a factor of the host response to infection. The immunologic interactions between chlamydial organisms and their host are extremely complex and not fully understood. The humoral and cellular immune responses elicited by these organisms may aid in control and elimination or actually be responsible for exaggerated inflammatory reactions and tissue damage. Primary focus on immunopathologic targets has been directed toward the chlamydial heat shock protein 60, which is thought to interact with certain inflammatory cell receptors resulting in cell activation.<sup>37</sup>

Following infection, the host's initial response is the formation of an acute local inflammatory reaction, which may resolve spontaneously with the eradication of the causative organism. However, the most frequent outcome is a chronic inflammatory process that may be protective but may also contribute to the pathogenesis of the disease process. Following infection, serovar-specific neutralizing antibodies to *C. trachomatis* can be detected in the patient's serum. However, serum antibody does not appear to play any significant role in recovery from superficial epithelial infections of the eye and genital tract. In contrast, secretory IgA and IgG in ocular secretions do appear to play a role in recovery from chlamydial ocular infection. Cell-mediated immune responses appear to be more important in recovery from genital tract infections, although they could be a key factor in the pathogenesis of both ocular and genital tract disease.

In both ocular and genital infections caused by *C. trachomatis*, the initial polymorphonuclear leukocytic (PMN) response is followed by a mixed infiltrate comprising lymphocytes, PMNs, plasma cells, macrophages, and eosinophils.<sup>38</sup> In the conjunctiva, urethra, and endocervix, the lymphocytes and other mononuclear cells aggregate to form lymphoid follicles with B cells and macrophages in the center, surrounded by a peripheral region comprised of T cells. An enhanced inflammatory response occurs following repeated reinfections both in naturally occurring infections and in animal models of both ocular and genital tract disease. These enhanced responses result in rapid clearance of *C. trachomatis* and thus increased difficulty in recovering the organisms from infected sites. Unfortunately, the severe inflammation also results in enhanced tissue damage and the formation of scars. These scars are a direct cause of the sight-threatening sequelae of trachoma,

namely entropion and trichiasis,<sup>39</sup> and may also be responsible, in part, for the loss of patency of the fallopian tubes, which could result in ectopic pregnancy or tubal infertility following several episodes of salpingitis.<sup>40</sup>

## **DIAGNOSIS**

A diagnosis of specific infection of the genital tract caused by *C. trachomatis* is totally dependent on the results of laboratory investigations. Isolation of *C. trachomatis* from clinical specimens has been the reference standard against which all other laboratory tests have been evaluated. However, culture of *C. trachomatis* requires laboratories with the capacity to perform either egg inoculations or cell culture since these bacteria are obligate intracellular pathogens. Successful isolation of *C. trachomatis* from clinical specimens varies among laboratories due to differences in methodologies and technical experience. The development and application of nonculture methods for the detection of *C. trachomatis* antigens or nucleic acid sequences have greatly advanced laboratory support for clinical management of these infections.

Test performance, cost, and ease of use are important factors that should be considered when choosing laboratory tests for the diagnosis of *C. trachomatis*. However, the same test may perform differently in different disease prevalence settings. For example, a test with a specificity of 99.5% would have a positive predictive value (PPV) of 65.7% in a population with 1% prevalence. When the test is used in a setting of 10% prevalence, the PPV would be increased to 91.3%. The number of false positive results generated by any test would be greatly reduced in high prevalence settings. Theoretical modeling can be applied as an aid to test selection, but this is dependent on accurate estimates of test performance. Newly developed and marketed tests are compared to imperfect standards and may use different statistical analyses to assess performance. This has resulted in a range of performance estimates. Although there are no laboratory tests that are 100% sensitive and 100% specific for *C. trachomatis*, amplified molecular approaches appear to demonstrate superior sensitivity and specificity to other nonculture and culture tests.<sup>41,42</sup>

## **Microscopy**

In men, a diagnosis of NGU is based on the microscopic finding of four or more PMNs per microscope field at  $\times 1000$  magnification without the presence of intracellular gram-negative diplococci. However, the finding of microscopic evidence of gonococcal infection does not preclude concurrent infection with *C. trachomatis* since mixed infections are commonly encountered. While five to more than ten PMNs per high-power field on smears made from endocervical swabs have been found to be associated with *C. trachomatis* infection in women by some workers, demonstration of inclusions in cells obtained from infected sites is relatively insensitive because inclusions are rarely detected in female genital tract exudates. Although intracytoplasmic inclusions have been detected in Pap smears obtained for cervical cytologic investigations, interpretation of these smears for *C. trachomatis* infection is difficult, and the sensitivity and specificity of the technique are unacceptably low.<sup>43</sup>

## Isolation of *Chlamydia trachomatis*

Chlamydiae are extremely labile, and therefore careful collection of specimens from the appropriate site is required in order to achieve optimal rates of isolation. The use of appropriate transport media and maintenance of a cold chain are essential for the successful isolation of these organisms. Appropriate sites to be sampled include the urethra in men, the endocervix and urethra in women, the rectum in both men and women, and the conjunctiva in cases of adult and neonatal conjunctivitis. Primary genital ulcerations, the urethra, endocervix, rectum, bubo aspirates, and draining sinuses may all be sampled in suspected cases of LGV.

Early studies on the role of *C. trachomatis* in genital tract disease depended on the isolation of these organisms in the yolk sacs of fertile hens' eggs. However, isolation in established cell lines has replaced eggs as the preferred method not only because chlamydiae cannot be readily propagated, but also because positive specimens are easier to detect. Unfortunately, high quality cell culture requires relatively specialized laboratories. A number of epithelial cell lines are permissive to *C. trachomatis* infection and support intracellular growth of the organism, and McCoy, HeLa 229, BGIMK, HEp-2, HL, and Vero cell lines have been used for chlamydial isolation. Most laboratories adopt a particular cell line for the growth of *C. trachomatis* on the basis of availability of the cell line and technical experience or impression. When using established cell lines, methods must be employed to facilitate the contact of chlamydiae with the eukaryotic cell membrane, and different techniques have been employed to facilitate this primary interaction, such as the application of diethylaminoethyl-dextran (DEAE-D) to reduce the ionic repulsion and/or centrifugation at approximately  $2500 \times g$  for 1 hour. In some cell culture systems, intracellular chlamydial growth is aided by the addition of 1  $\mu\text{g/mL}$  of cycloheximide to the culture medium to inhibit eukaryotic protein synthesis.

In all culture systems, cells are grown on glass coverslips in flat-bottomed shell vials or in the wells of microtiter plates,<sup>44</sup> and specimens are inoculated onto the surface of the confluent cell monolayer. After incubation at 35°C for 48 to 72 hours, the monolayers are fixed and stained, and characteristic inclusion bodies may be detected. The inclusions may be visualized following staining with Lugol's iodine, with Giemsa stain, or with fluorescein-conjugated monoclonal antibodies to a genus-specific epitope of the LPS or a species-specific epitope of the MOMP. Staining with monoclonal antibodies is preferred because the staining technique is more sensitive and specific than either iodine or Giemsa staining and the inclusions can be visualized earlier in the life cycle.<sup>45</sup> Monoclonal antibody stains directed against the MOMP allow for increased specificity since they are species-specific for *C. trachomatis*.

## Antigen Detection

Two antigenic targets on chlamydiae, LPS and the MOMP, have been exploited commercially in the development of non-culture diagnostic tests. Chlamydial LPS is genus-specific, and antibodies to the LPS will cross-react with all members of the family Chlamydiaceae including human and other animal pathogens.<sup>46</sup> Enzyme immunoassay (EIA) tests and some direct fluorescent antibody (DFA) tests detect chlamydial LPS.

The EIA tests are designed to detect organisms in specimens obtained from the endocervix and can provide a result in approximately 20 minutes. In contrast, the DFA test requires a specialized fluorescence microscope but can be used to detect infection using slides prepared from endocervical, urethral, rectal, pharyngeal, and conjunctival specimens. The MOMP-based DFA is the only antigen test capable of identifying *C. trachomatis*. There is no doubt that there are both advantages and disadvantages of each of these techniques. For example, DFA requires careful collection of appropriate specimens and preparation of the slides used for microscopy. In addition, a skilled microscopist is required to correctly interpret smears that may contain artifacts which fluoresce nonspecifically. Fluorescence microscopy is undoubtedly tiring, and therefore DFA cannot be recommended for those laboratories that process large volumes of specimens. In contrast, the EIA can be semi-automated and can be performed by less-skilled personnel. Problems related to false positive results have largely been overcome by some manufacturers by including a confirmatory blocking antibody test in the format. In these tests, all positive tests are repeated in the presence of specific antibody to chlamydia. If the original test is a true positive, the second confirmatory test should produce a significantly reduced signal. The sensitivities and specificities of antigen detection methods range from 60% to 80% and over 95%, respectively.

## Nucleic Acid Hybridization Assays

DNA and RNA probe sequences have been developed to detect complementary sequences specific to those of *C. trachomatis*. They are similar in technical requirements to EIA tests, but they have slightly better performance characteristics. The primary advantage is that specimens can be tested up to 7 days after collection, and refrigeration is not required during storage.

## Nucleic Acid Amplification Tests

Several nucleic acid amplification tests are commercially available for the detection of specific chlamydial nucleotide sequences which may be present in clinical specimens, including polymerase chain reaction (PCR), strand displacement assay (SDA), ligase chain reaction (LCR), and transcription-mediated amplification (TMA). In general, these assays have demonstrated extremely high sensitivities when compared to culture.<sup>47–49</sup> The increased sensitivity is based on the theoretical ability to detect a single copy of the target sequence. The tests are designed to target sequences found in multiple copies per organism. There are up to 10 copies of the cryptic plasmid within *C. trachomatis*, and this is the target for the PCR, SDA, and LCR. A few cryptic plasmid-free *C. trachomatis* strains have been reported, but these do not appear to be widespread. The TMA test detects specific 23S ribosomal RNA in *C. trachomatis*, which may exist in up to 2000 copies per organism.<sup>50</sup> Both the cryptic plasmid and 23S rRNA are found in all serovars of *C. trachomatis* including the L serovars that cause LGV. The higher sensitivity of DNA amplification techniques compared to culture has necessitated the development of algorithms to determine whether positive results obtained by these new molecular assays are, in fact, true or false positives. This determination is particularly important when culture

results are found to be negative. Recent evaluations have moved away from using culture data by employing methods of rotating standards or a patient infection status based on multiple amplification test results. The sensitivity and specificity of these various assays are greater than 85% and 98%, respectively.<sup>51</sup>

One major advantage of these amplified molecular technologies is the ability to detect *C. trachomatis* DNA in urine specimens obtained from both men and women. The use of noninvasive specimens has led to better understanding of prevalence and improved disease management through expansion of screening programs for *C. trachomatis*. One possible drawback of urine specimens is the need for liquid transport to the laboratory. Vaginal swabs collected either by the patient or by a health-care provider have been shown to be acceptable and at least equal in performance to urine. Swab specimens are generally easier to transport to the laboratory since there is no possibility of leakage and potential contamination of other specimens.

The enhanced sensitivity of these tests can also lead to potential problems when implemented by laboratories that are not familiar with or physically set-up for nucleic acid amplification. Specimens must be processed in a unidirectional manner to prevent amplified material contaminating the initial processing stages. Laboratorians must adhere to strict guidelines set forth by manufacturers to ensure quality results. Additionally, reagents for these tests are sometimes difficult to produce in a consistent manner and have occasionally caused variability in laboratory results. The LCR test was withdrawn from the market after experiencing such difficulties in production.

Though these tests are clearly better in performance and offer the greatest range of specimen types, including endocervical, urethral, vaginal, rectal, and pharyngeal swabs and urine, they are also the most expensive on the market. Cost may preclude routine use in many settings, particularly in developing countries.

### Serologic Tests

The chlamydial complement fixation test (CFT), which measures antibody against group-specific lipopolysaccharide antigen, has, in the past, been widely used as an aid in the diagnosis of LGV and psittacosis, both of which elicit significant antibody responses as a result of systemic immune stimulation. Unfortunately, the sensitivity of the test is low in those chlamydial infections that are restricted to superficial epithelial surfaces only. Thus, while titers equal to or greater than 1:64 are regularly measured in the serum of patients with proven psittacosis or LGV, only 50% of patients with proven oculogenital infection have titers equal to or greater than 1:16. In uncomplicated genital tract infections such as acute urethritis or cervical infection, CFT reactor rates are usually even lower, with only 15% of men with urethritis and 40% of women with cervical infection having titers equal to or greater than 1:16.<sup>52</sup>

The microimmunofluorescence (micro-IF) test was initially developed for serotyping strains of *C. trachomatis* isolated from the eye and genital tract but was soon adapted to measure antibody responses in patients with proven chlamydial infections. Although the original micro-IF method was complicated, involving the titration of sera against numerous antigens, it was

found to have many advantages when compared to the complement fixation test. Not only did it detect type-specific antibody but by using different conjugated antisera it could be used to detect different immunoglobulin classes. Above all, it was much more sensitive than the CFT with a larger proportion of patients developing an antibody response and at higher titer. Thus, patients with LGV tend to have broadly cross-reactive micro-IF antibody titers that are often greater than 1:256. As the full micro-IF test is extremely laborious to perform, several efforts to simplify the test have been made. Thus, several groups have either used a single, broadly cross-reactive antigen (either serotype E or L<sub>2</sub>)<sup>53</sup> in the test or have included the majority of serovars in various antigen pools.<sup>54,55</sup>

The micro-IF test tends to be positive in over 90% of women with cervical infection and 80% of men with proven chlamydial urethritis. Antichlamydial IgG can be detected in the sera of all babies with neonatal chlamydial infection, but this may reflect passive transfer of specific antibodies from the infected mother. In contrast, specific IgM antibodies may be detected in approximately one-third of babies with neonatal chlamydial conjunctivitis and all babies with neonatal pneumonia caused by *C. trachomatis*. Unfortunately, the prevalence of antichlamydial antibodies is extremely high, especially among sexually active adults in developing countries where STDs are common. This situation is largely a reflection of previous exposure to these organisms rather than recently acquired disease.

While there is little doubt about the value of the micro-IF test as an epidemiologic tool, the general use and frequent abuse of the original test and its variants has largely discredited its use for the diagnosis of chlamydial infection in individual cases. It is generally agreed that the test is of little value in the diagnosis of uncomplicated genital tract infection in both men and women, but is of value in establishing a diagnosis in cases of LGV and chlamydial neonatal pneumonia.

## TREATMENT

### Uncomplicated Genital Tract and Ocular Infections in Adults

Those antimicrobial agents which have significant activity against *C. trachomatis* include the tetracyclines, macrolides, rifamycins, sulfonamides, clindamycin, and some of the fluoroquinolones. In addition, penicillin, ampicillin, and amoxicillin all have some activity against these organisms, although only amoxicillin is included in the current Centers for Disease Control and Prevention (CDC) treatment guidelines.<sup>56</sup> The aminoglycosides, cephalosporins, and aminocyclitols appear to have no activity against *C. trachomatis* whatsoever. The treatment of choice for uncomplicated genital tract infections in both men and women has remained doxycycline 100 mg orally twice daily for 7 days, with erythromycin base 500 mg or erythromycin ethylsuccinate 800 mg orally four times daily for 7 days as alternatives. The only quinolone currently recommended for treatment of uncomplicated *C. trachomatis* infections is ofloxacin at a dosage of 300 mg orally twice daily for 7 days.

Azithromycin, an azalide antibiotic related to the macrolides, can be given as a single 1-g oral dose and has been found to be as effective as a 7-day course of doxycycline in the treatment of uncomplicated chlamydial genital tract infections

in both men and women. This single-dose therapy has been hailed as a major breakthrough in the management of these infections, but azithromycin is expensive and is often not available in settings where its use would be appreciated most, namely, in resource-poor settings in developing countries where compliance with a 7-day course of doxycycline is likely to be poor.

Doxycycline and ofloxacin are contraindicated during pregnancy and lactation, and the safety and efficacy of azithromycin under these circumstances have not been fully established. Erythromycin remains the treatment of choice for chlamydial infections in pregnancy. However, many women are unable to tolerate the 500-mg-four-times-daily regimen and a lower dose (250 mg four times daily) for a longer period (14 days) may be acceptable. Alternatives include amoxicillin 500 mg orally three times daily for 7 days and clindamycin 450 mg orally four times daily for 14 days. Clinical presentations in which the likelihood of chlamydial infection is high enough to warrant inclusion of presumptive treatment for *C. trachomatis* include acute urethritis, pelvic inflammatory disease (PID), epididymitis in young men, and cases of vaginal discharge in women at risk of an STD. Syndromic case management, which is advocated by the World Health Organization for the management of STDs,<sup>57</sup> particularly in developing countries and where diagnostic facilities are poor, combines antichlamydial therapy with that for acute gonococcal infection in cases of acute urethritis and epididymitis and with that for gonococcal and anaerobic infection or bacterial vaginosis or trichomoniasis in cases of PID and vaginal discharge. Likewise, combination therapy that will cover both gonococcal and chlamydial infection is provided in cases of proctitis diagnosed in MSM. Provision of appropriate single-dose therapy for gonococcal infection depends on antimicrobial susceptibilities of local isolates of *N. gonorrhoeae*. Thus, ceftriaxone 125 to 250 mg or spectinomycin 2 g, both as an intramuscular injection, or cefixime 400 mg orally, ciprofloxacin 500 mg orally, or ofloxacin 400 mg orally as a single dose can all be combined with a course of doxycycline or a single dose of azithromycin to provide broad-spectrum coverage for gonococcal and chlamydial disease. Oral therapies recommended for the treatment of uncomplicated genital tract infections are also effective in the treatment of cases of adult inclusion conjunctivitis.

### Neonatal Infections

Oral erythromycin in doses of 50 mg/kg body weight per day in four divided doses for 10 to 14 days is the treatment of choice for both neonatal chlamydial conjunctivitis and pneumonia.<sup>56,57</sup> Topical therapy for neonatal ocular infection is not recommended since it fails to eradicate chlamydial carriage in the nasopharynx, which can act as a source of infection of the lungs and reinfection of the conjunctiva. Unfortunately, ocular prophylaxis with silver nitrate, which is routinely given to prevent gonococcal ophthalmia neonatorum in some countries, has no effect on acquisition of chlamydial conjunctival infection. In addition, prophylaxis with tetracycline eye ointment will prevent neonatal ocular infection but has little effect on prevention of neonatal pneumonia. All mothers of infants with *C. trachomatis* neonatal infections should be treated with an appropriate course of antichlamydial therapy and investigated for other sexually transmitted infections. Prenatal screening

programs have been introduced in several industrialized countries. However, the high cost of very sensitive molecular screening techniques has limited the implementation of such programs in many countries that would benefit most from their introduction.

### Management of Lymphogranuloma Venereum

Treatment of LGV is aimed not only at curing the infection but also preventing the complications that may accompany the disease, such as scarring and disfigurement. Thus, fluctuant inguinal and femoral lymph glands should be aspirated through intact skin using a wide-bore needle to prevent the formation of inguinal or femoral ulcerations. Repeat aspirations may be required even though appropriate antimicrobial chemotherapy has been initiated.

As in other chlamydial infections of the genital tract, doxycycline is the treatment of choice for LGV, but prolonged therapy (100 mg orally twice daily for 21 days) may be required for complete resolution. Alternatively, erythromycin base 500 mg orally four times a day for the same duration may be provided. In some tropical countries, the erythromycin regimen may be preferred to provide adequate therapy for chancroid (caused by *Haemophilus ducreyi*), a disease with which LGV may frequently be confused.

### PREVENTION

As with all other STDs, sex partners of patients who have LGV should be examined and treated with a course of antichlamydial therapy if they have had sexual contact with the index patient within a month preceding the onset of symptoms in the index case.

# Psittacosis

THOMAS J. MARRIE

## INTRODUCTION

Psittacosis was first described by Ritter in 1879.<sup>1</sup> At that time he was investigating a household outbreak of a severe respiratory illness that was associated with contact with sick parrots. In 1892 Morange applied the name *psittacosis* (Greek *psittakos*, parrot) to this illness because of its association with sick parrots. In 1930 the causative agent, *Chlamydia psittaci*, was isolated at about the same time by Bedson in the United Kingdom, Krumwiede in the United States, and Lemonthol in Germany.<sup>2</sup>

## ORGANISM

Chlamydiae are obligate intracellular prokaryotes with a small genome of approximately 1.2 megabases. Some strains of *C. psittaci* contain a plasmid.<sup>2</sup> The family Chlamydiaceae has two genera: *Chlamydia* with *C. trachomatis*, *C. muridarum*, and *C. suis* as species; and *Chlamydophila* with *C. abortus*, *C. caviae*, *C. felis*, *C. pecorum*, *C. pneumoniae*, and *C. psittaci* as species. *Chlamydophila psittaci* has eight serovars, six of which have been isolated from birds (A through F) and two (WC and M 56) that have been isolated from mammals. Chlamydiae exhibit morphologic and structural similarities to gram-negative bacteria. The life cycle is initiated when an elementary body (the extracellular form) attaches to a susceptible epithelial cell. The elementary body then enters the epithelial cell by receptor-mediated endocytosis, where it undergoes reorganization into a much larger replicating form, the reticulate body. The reticulate body divides by binary fission to produce an ever-enlarging inclusion. The morphology of the elementary and reticulate bodies of *C. psittaci* and *C. trachomatis* are similar. *C. psittaci* forms multiple small inclusions in a single infected cell, with each infected elementary body developing its own inclusion. Kaltenboeck and colleagues<sup>3</sup> compared the sequences of the *ompA* gene (which encodes major outer membrane protein) of 10 strains of *C. psittaci*, 11 strains of *C. pecorum*, one *C. pneumoniae* strain, and two *C. trachomatis* strains. Two clusters were present: *C. trachomatis* and another cluster consisting of three major groups of *ompA* alleles: the psittacosis group, *C. pneumoniae*, and the polyarthritidis group (ruminant and porcine chlamydial alleles).

## EPIDEMIOLOGY

It is likely that all birds are susceptible to infection with *C. psittaci*. Over 150 avian species (57 of the parrot family) representing 10 orders have been documented as hosts for

this microorganism. These include members of the parrot family (macaws, cockatoos, parakeets, budgerigars), finches (canaries, bullfinches, goldfinches, sparrows), poultry (hens, ducks, geese, turkeys), and pigeons, pheasants, egrets, gulls, and puffins. Birds transmit the infection to their nestlings, which in turn shed the organism during periods of both illness and health. In bird populations there is a baseline prevalence of 5% to 8% carriage of *C. psittaci*. This may increase to 100% when the birds are subjected to the stress of shipping, crowding, and breeding. Strains from turkeys and other psittacine birds are most virulent for humans.<sup>2,4</sup> Most human infections result from avian strains of *C. psittaci*, but other strains from animals are occasionally implicated. The disease has occurred in ranchers following exposure to infected goats, cows, and sheep.<sup>5</sup> Endocarditis has been attributed to avian and non-avian strains, and cats have spread feline pneumonitis to humans and other mammals.<sup>6,7</sup> The organism is resistant to drying and can remain viable for a week at room temperature.

Infected birds excrete *C. psittaci* in feces for several months. Nasal and lacrimal secretions may be infectious.<sup>8</sup> Transmission via eggs has been demonstrated in ducks. In experimental avian infections, the incubation period is 5 to 10 days. In turkeys, virulent *C. psittaci* strains cause pericarditis, weight loss, air sacculitis, and bronchopneumonia.<sup>8</sup> The mortality rate is low in natural infection.<sup>8</sup> In infected ducks and geese, conjunctivitis, rhinitis, polyserositis, pericarditis, and splenomegaly are common findings.<sup>8</sup> In pigeons, air sacculitis, hepatomegaly, and splenomegaly occur. In psittacine birds, splenomegaly, hepatomegaly, enteritis, sinusitis, and air sacculitis are frequently seen.<sup>8</sup>

Psittacosis is distributed widely. In northern climates sporadic cases are acquired by contact with imported birds that have not been quarantined and treated with tetracycline prior to sale. Psittacosis in tropical countries is more likely to occur where parrots are caged and kept as household pets. Psittacosis is an occupational hazard for abattoir workers (turkeys, chickens), farmers or ranchers (ducks, turkeys), laboratory workers (technicians in veterinary research facilities can be involved in outbreaks), pet shop employees (psittacine birds), and veterinarians.<sup>9</sup> About 100 to 250 cases of psittacosis are reported to the Centers for Disease Control and Prevention (CDC) in Atlanta each year.<sup>10</sup> Sporadic psittacosis is often underdiagnosed. In a recent study of 149 patients with pneumonia treated on an ambulatory basis, the author found that two cases (1.3%) were due to *C. psittaci*. Neither case was suspected by the physician to be psittacosis.

## DISEASE

The clinical spectrum of *C. psittaci* infection is wide, ranging from a subclinical illness to rapidly progressive pneumonia.<sup>2</sup> The incubation period is from 5 to 15 days. Fever, rigors, sweats, and headache are common. Cough occurs in from 50% to 100% of patients, but it usually appears late in the course of illness and usually is nonproductive.<sup>10</sup> The cough, however, may be productive of mucoid sputum, and rarely there is hemoptysis. Some patients, up to 19% in one series, have no respiratory symptoms.<sup>11</sup> There is also a mononucleosis-like form of the illness with fever, pharyngitis, hepatosplenomegaly, and lymphadenopathy. A typhoidal form presents with fever, bradycardia, and malaise. In a series of 135 cases

*Chlamydia psittaci*

from Australia, there were five modes of presentation: (1) fever with rigors, sweats, and constitutional symptoms but no localizing features, occurring in 41% of the patients; (2) prominent cough and occasionally dyspnea in association with fever in 33%; (3) severe headaches suggestive of meningitis; (4) diarrhea, which occurred in two patients; and (5) pharyngitis, which occurred in 21 patients.<sup>12</sup> An alteration of mental status was noted in 12%.

There are many extrapulmonary manifestations of psittacosis. These include Horder's spots (a pink, blanching maculopapular eruption resembling the rose spots of typhoid fever), acrocyanosis, superficial venous thrombosis, and splinter hemorrhages. Panniculitis, erythema multiforme, and erythema nodosum are cutaneous manifestations.<sup>13</sup> Encephalitis, meningitis, cerebellar involvement, cranial nerve palsies, intracranial hypertension, and transverse myelitis are central nervous system manifestations.<sup>14</sup> Acute renal failure,<sup>15</sup> pancreatitis, and thrombocytopenic purpura have also complicated psittacosis.<sup>16</sup> Other manifestations include reactive arthritis<sup>17</sup> and hemophagocytosis.<sup>18</sup>

Psittacosis during pregnancy is uncommon, but when it occurs it may be severe. An outbreak of sheep-associated psittacosis in the Faroe Islands in 1938 resulted in infection of 14 pregnant women, 11 of whom died.<sup>19</sup> Beer and associates reported two cases of sheep-associated psittacosis involving pregnant women who were at 34 and 36 weeks' gestation, respectively, at the time of infection.<sup>6</sup> Helm and coworkers<sup>11</sup> reviewed six definite and three possible cases of sheep-associated *C. psittaci* infection during pregnancy. These patients had marked thrombocytopenia, low-grade disseminated intravascular coagulation, and liver and renal dysfunction. Two of the pregnancies ended in spontaneous abortion and three in intrauterine death. Ghermen and coworkers<sup>20</sup>

recently reported a 19-year-old woman who developed *C. psittaci* pneumonia, at 32 weeks' gestation, following exposure to a parakeet. Cesarean section was necessary because of worsening respiratory status and fetal compromise. Acute and chronic inflammatory cells were present in the placenta. *C. psittaci* appears to have a predilection for the placenta.

Severe respiratory insufficiency due to psittacosis is uncommon, with only 12 reported cases from 1963 to 1993. Ten of these 12 had a history of exposure to birds. Seven had neurologic manifestations, six had gastrointestinal symptoms, and four were in acute renal failure requiring hemodialysis.<sup>21</sup> Eight patients (67%) died, three within 48 hours of admission.

The white blood cell count is usually normal in psittacosis. Eosinophilia may be seen during convalescence. Macfarlane and colleagues<sup>22</sup> compared the radiographic features of 10 patients with *C. psittaci* pneumonia, 49 with Legionnaire's disease, 91 with pneumococcal pneumonia, and 46 with mycoplasma pneumonia. No distinctive pattern was seen for any group. Forty percent of the psittacosis patients had multilobe involvement, and 20% had a pleural effusion. In this series, none of the patients with psittacosis showed radiographic deterioration following admission, as compared with 65% of the patients with Legionnaire's disease, 52% of those with bacteremic pneumococcal pneumonia, and 25% with mycoplasma pneumonia. Fifty percent of the patients with psittacosis pneumonia showed clearing of the radiographic opacities by 4 weeks; however, 30% were still unresolved by 12 weeks. In a review of 43 cases of psittacosis, Coutts and colleagues<sup>23</sup> found that 12 (28%) had a normal chest radiograph. Segmental consolidation was most frequent (31%); 21% had lobar consolidation, and 19% had multilobar involvement.

The pleural fluid in psittacosis may have a high adenosine deaminase level.<sup>24</sup> This could result in confusion with

tuberculosis, since an adenosine deaminase level of greater than 43 IU/L in pleural fluid is believed to be sensitive and specific for tuberculosis.

## PATHOGENESIS AND IMMUNITY

Human infection with *Chlamydia psittaci* follows inhalation of contaminated aerosols shed by infected birds. The mechanism whereby *C. psittaci* is introduced into a flock of birds is poorly understood. Many investigators think that wild birds, which can be infected by the same strains as domestic flocks, play a major role in this process.<sup>25</sup> It is likely that vertical transmission occurs in flocks.<sup>25</sup>

In turkeys *C. psittaci* infects epithelial cells and macrophages in the respiratory tract.<sup>26</sup> This is followed by septicemia and localization of the organisms in epithelial cells and macrophages in various organs.<sup>26</sup> It is still unclear whether humoral or cell-mediated immunity is the most important host defense against *C. psittaci*. The major outer membrane protein (MOMP) has been identified as a protective antigen.<sup>27,28</sup> Plasmid DNA expressing *C. psittaci* serovar A MOMP was used to vaccinate turkeys and was shown to be effective.<sup>29</sup>

## DIAGNOSIS

A high index of suspicion is necessary to make the diagnosis of psittacosis. Confirmation is by serologic test—the microimmunofluorescence test is more sensitive and species-specific than the complement fixation test (CF). *C. psittaci* may also be isolated in tissue culture, but most laboratories do not have the capability of cultivating chlamydiae. An antibody titer of 1:64 by the CF test is considered diagnostic. A fourfold rise in titer is also diagnostic. The CF test is genus-specific and does not distinguish *C. trachomatis* from *C. pneumoniae* or *C. psittaci* infection. *C. psittaci* DNA can be detected in respiratory secretions using polymerase chain reaction. Wong and associates<sup>30</sup> studied 78 patients in whom a diagnosis of psittacosis was made on the basis of appropriate clinical symptoms following exposure to sick birds. The CF test identified 36 of 78 (46%) as positive, while the microimmunofluorescence (MIF) test identified 48 of 78 (61%). The investigators used eight strains of *C. psittaci* in the MIF test. Others have noted that the MIF test can be falsely negative.<sup>20</sup> Thus, more than one strain of *C. psittaci* should be used in the MIF test. Wong and coworkers<sup>30</sup> noted four serologic reaction patterns among their 78 patients: (1) positive CF and MIF tests (46%), (2) anticomplementary or negative CF test and positive MIF test (15%), (3) positive serologic response to *C. pneumoniae* (9%), and (4) negative antibody titer using both CF and MIF tests (29%).

## TREATMENT AND PROGNOSIS

Treatment is with tetracycline or doxycycline for 10 to 21 days.<sup>2</sup> Response to treatment is usually prompt. Some patients have severe fatigue that persists for 2 to 3 months following resolution of the acute illness. A longer course of treatment has been recommended to prevent relapse. Erythromycin is an alternative to treatment with a tetracycline but may be less efficacious in severe cases. There is less than a 1% mortality rate in treated cases.

## PREVENTION AND CONTROL

Infected birds should be treated with tetracycline, chlorotetracycline, or doxycycline for at least 45 days. Ideally, all imported birds should be treated prophylactically for *C. psittaci*. The Centers for Disease Control and Prevention has issued recommendations for the control of *C. psittaci* among humans and birds, and these should be used whenever a case of psittacosis is encountered. All cases of psittacosis should be reported to a medical officer of public health for appropriate follow-up and tracing of infected birds.<sup>31</sup>

## D. RICKETTSIAL AND EHRLICHIAL INFECTIONS

50

### Spotted Fever Group Rickettsioses

DANIEL J. SEXTON  
DAVID H. WALKER

#### INTRODUCTION

*Rickettsia* species of the spotted fever group (SFG) cause human diseases in tropical Africa, Asia, Australia, South America, Central America, and Mexico. During the past decade, several new rickettsial diseases have been discovered (e.g., tick-associated lymphadenopathy and flea-borne spotted fever), and the recognized geographic range of known rickettsial diseases such as rickettsialpox has expanded from urban to suburban and rural areas, and African tick bite fever and Japanese spotted fever to new countries. Rickettsial infections are often neglected and are poorly recognized by physicians in many tropical and subtropical locations. Indeed, despite a number of recent reports describing rickettsial diseases in new locations or the discovery of new rickettsiae, medical science has focused insufficient efforts in the diagnosis and antimicrobial treatment of rickettsial infections in subtropical and tropical areas, and thus it is likely that much remains to be discovered.

#### ORGANISMS

Rickettsiae are small ( $0.3 \times 1.0 \mu\text{m}$ ) obligately intracellular bacteria with a gram-negative cell wall that reside free in the cytosol of human endothelial cells and various cells of their arthropod hosts. The family Rickettsiaceae contains the genera *Rickettsia* and *Orientia*. The genus *Rickettsia* is divided into the typhus and spotted fever groups on the basis of antigenic differences in the immunodominant lipopolysaccharides (LPS) the presence of outer membrane protein A (OmpA) in SFG rickettsiae, and evolutionary genetic relationships.<sup>1</sup> OmpA serves as an adhesin and contains a series of hydrophilic tandem repeat units that vary in number and order, and OmpB, also an adhesin, is a 135-kD S-layer protein, which is the processed form of a 168-kD precursor.<sup>2-6</sup> Species- and strain-specific epitopes are located on these proteins.<sup>7-10</sup> Molecular approaches to the taxonomy of *Rickettsia* species reveal very close genetic relationships that in other genera such as

*Orientia* would lump many of these organisms into a smaller number of named species.<sup>11,12</sup> For example, *R. africae* and *R. parkeri* show minimal differences as do *R. japonica* and the proposed new species "*R. heilongjiangensis*."<sup>13,14</sup> The genetic conservatism of these bacteria may be explained by their intracellular location and prolonged survival in arthropod hosts mitigating immune selective pressure. Rickettsiae have gone through remarkable gene reduction with a genome as small as 1.1 Mb and rely upon the cytosolic environment and their effective transport systems for amino acids, phosphorylated sugars, and ATP as well as utilizing their own metabolic enzymes. Approximately one-half of the known species of SFG rickettsiae cause disease in humans; the remainder have been isolated only from arthropods. Species of SFG rickettsiae known to cause human disease include *R. rickettsii*, *R. conorii*, *R. africae*, *R. australis*, *R. sibirica*, *R. japonica*, *R. honei*, *R. parkeri*, *R. slovaca*, *R. felis*, *R. aeschlimannii*, and *R. akari*.

During the first decade of the 20th century, a young American investigator, Howard Ricketts, discovered that ticks were vectors of a then mysterious illness known as Rocky Mountain spotted fever (RMSF), that the causative organism (which he isolated in guinea pigs) circulated in nature between ticks and mammals, and that infected ticks transmitted the causative organism to their progeny.<sup>15</sup> Ricketts's discoveries paved the way for later investigators, who discovered other rickettsial diseases occurring between the tropics of Capricorn and Cancer, which are the focus of this chapter.

#### EPIDEMIOLOGY

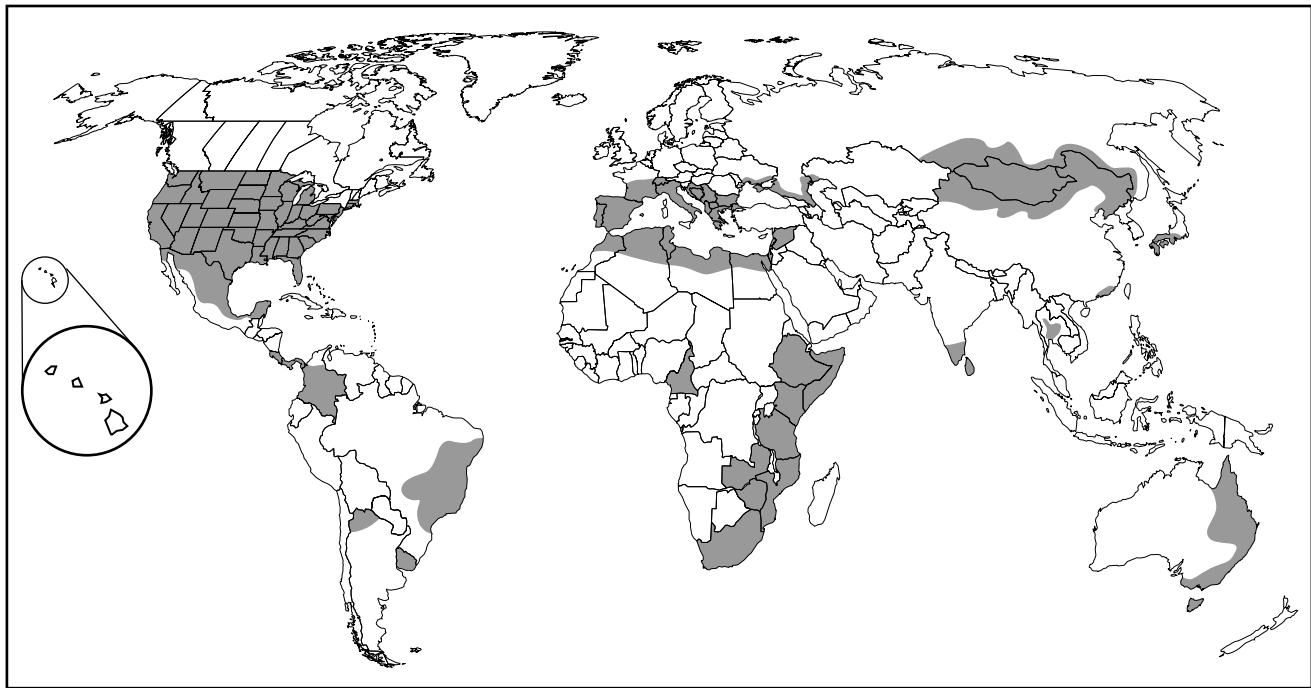

Although SFG rickettsioses were identified in some tropical countries in the first half of the 20th century—*R. conorii* (Tunisia, Kenya, South Africa, India), *R. rickettsii* (Mexico, Colombia, Brazil), and *R. australis* (Australia)—in general, rickettsiology had scarcely investigated these parts of the world.<sup>16-20</sup> Recently, investigations using powerful and sensitive molecular tools have identified a myriad of varieties of SFG rickettsiae in patients and arthropods associated with disease in many parts of the world, including *R. africae*, *R. parkeri*, *R. honei*, *R. japonica*, *R. felis*, *R. sibirica* (mongolotimoniae strain), *R. slovaca*, and *R. aeschlimannii*.<sup>21-23</sup> The geographic distribution of the rickettsiae is not as narrowly focal as was believed; for example, *R. sibirica* strains cause disease in Asia, Europe, and Africa; *R. africae*/*R. parkeri* strains in Africa, Eurasia, North and South America; and *R. honei* in southern Australia and Thailand.<sup>24,25</sup> In some instances, such as *R. felis*, which is maintained transovarially in cat fleas that have been distributed throughout the world in felines, or *R. akari* that is maintained transovarially in mites carried by domestic mice, a worldwide distribution can be explained. Others rely upon unproven hypotheses such as transportation of infected ticks on migratory birds.

SFG rickettsiae are associated mainly with ticks, with the exceptions of *R. akari* (*Liponyssoides sanguineus*, mites) and *R. felis* (*Ctenocephalides felis*, cat fleas; Table 50-1). The geographic distribution of the *Rickettsia* is determined largely by

Table 50-1 Epidemiology of Spotted Fever Group Rickettsioses Listed in Order of Decreasing Clinical Severity

Agent	Disease	Geographic Distribution	Maintenance in Nature	Human Transmission
<i>R. rickettsii</i>	Rocky Mountain spotted fever, Brazilian spotted fever	North and South America	Transovarial maintenance in <i>Dermacentor</i> , <i>Rhipicephalus</i> , and <i>Amblyomma</i> ticks; less extensive horizontal transmission from tick to mammal to tick	Tick bite
<i>R. conorii</i>	Boutonneuse fever, Mediterranean spotted fever, Kenya tick typhus, Israeli spotted fever, Indian tick typhus, Astrakhan spotted fever	Mediterranean basin, Africa, Asia	Transovarial maintenance in <i>Rhipicephalus</i> ticks	Tick bite
<i>R. sibirica</i>	North Asian tick typhus	Russia, China, Mongolia, Pakistan, Kazakhstan, Kirgiziya, Tadzhikistan, France, Niger, Mali, South Africa	Transovarial maintenance in <i>Dermacentor</i> , <i>Haemaphysalis</i> , and <i>Hyalomma</i> ticks; horizontal transmission from tick to mammal to tick	Tick bite
<i>R. japonica</i>	Japanese spotted fever	Japan, China	Presumably a transovarial tick host	Tick bite
<i>R. australis</i>	Queensland tick typhus	Eastern Australia	Transovarial transmission in <i>Ixodes</i> ticks	Tick bite
<i>R. akari</i>	Rickettsialpox	United States, Ukraine, Croatia, possibly worldwide	Transovarial transmission in <i>Liponyssoides sanguineus</i> mites; horizontal transmission from mite to mouse to mite	Mite bite
<i>R. honei</i>	Flinders Island spotted fever	Southern Australia, Thailand	Transovarial transmission in <i>Aponomma</i> ticks	Tick bite
<i>R. africae/R. parkeri</i>	African tick bite fever	Sub-Saharan Africa, Caribbean, North and South America	Transovarial maintenance in <i>Amblyomma</i> ticks	Tick bite
<i>R. felis</i>	Flea-borne spotted fever	North and South America, Africa, Europe, presumably worldwide	Transovarial transmission in <i>Ctenocephalides felis</i> fleas	Unknown
<i>R. slovaca</i>	Tick-borne lymphadenopathy; <i>Dermacentor</i> -borne necrosis, eschar, lymphadenopathy	Europe	Transovarial transmission in <i>Dermacentor</i> ticks	Tick bite
<i>R. aeschlimannii</i>	Not named	Southern Europe, Africa	Presumably transovarial transmission in <i>Hyalomma</i> ticks	Tick bite

Rickettsiae of the Spotted Fever Group

that of its arthropod host in which vertical transovarian transmission from one generation to the next is the major mechanism of maintenance in nature.<sup>26</sup> Highly pathogenic bacteria such as *R. rickettsii* have a deleterious effect on their tick host resulting in death of the infected tick lineage after several generations of transovarian passage.<sup>27</sup> This harmful interaction correlates with a low prevalence (less than one *R. rickettsii*-infected *Dermacentor* tick per 1000 ticks) even in endemic regions.<sup>28</sup> These highly virulent rickettsiae rely upon their virulence for horizontal transmission to establish new infected tick lines by growth in a vertebrate host and generation of high titers of rickettsiae in the blood to be acquired by feeding ticks. In contrast, some less pathogenic organisms such as *R. africae* are present in up to 80% of their host ticks with which they appear to have a successful relationship. Some SFG species such as *R. peacockii*, *R. montanensis*, *R. massiliae*, *R. amblyommii*, and *R. rhipicephali* have never been associated with human disease.

SFG rickettsiae are transmitted during feeding of the tick or mite when rickettsiae are inoculated in arthropod saliva into the person's skin. The epidemiology thus is determined by climatological factors that affect tick activity and human activities that bring persons in contact with infected ticks. Tick prevalence and questing behavior seeking a host for a blood meal are affected by temperature and humidity, which vary dramatically from one region to another. Indeed, in most endemic locations there is a demarcated seasonal occurrence of rickettsial infections.

*Rickettsia conorii* is highly associated with *Rhipicephalus sanguineus* brown dog ticks, particularly in the Mediterranean basin including southern Europe, North Africa, and the Middle East. The rarity of recognized tick bite suggests transmission by

larval and nymphal ticks. Likely the most prevalent SFG rickettsiosis in the world, African tick bite fever was recognized as a distinct illness by the 1930s although subsequently confused with *R. conorii* infections. Nearly 60 years later, the agent was identified as *R. africae*, which is transmitted by highly aggressive *Amblyomma hebraeum* ticks in southern Africa and by *A. variegatum* in this tick's geographic distribution in sub-Saharan Africa and the West Indies. Outbreaks involving clusters of travelers in rural areas and soldiers in southern Africa and many cases among febrile patients in Cameroon suggest that *R. africae* may cause a very high incidence of infections among indigenous persons as well as travelers returning from endemic regions.<sup>29</sup>

The extremely close genetic and antigenic relationship between *R. africae* and *R. parkeri* and the recent description of an African tick bite fever-like disease in a patient infected with *R. parkeri* in Virginia suggests that the same or similar disease occurs in North America where *Amblyomma maculatum* and *A. americanum* are the tick hosts. A similar SFG rickettsial disease in Uruguay associated with *A. triste* tick bite and the presence of *R. parkeri* in *Amblyomma* ticks in Brazil and Uruguay may indicate the distribution of this infection throughout the Americas where infected *Amblyomma* vectors occur.

RMSF has been documented in the United States, Mexico, Costa Rica, Panama, Colombia, Brazil, and Argentina.<sup>30–32</sup> The principal vectors of *R. rickettsii* in the tropics are *R. sanguineus* and *A. cajennense*. However, *A. cajennense* has also been described as a host of an unidentified SFG rickettsia in Veracruz, Mexico, and *R. rickettsii* has also been isolated from rabbit ticks (*Haemaphysalis leporispalustris*) collected in Costa Rica.<sup>33,34</sup> *R. australis* infection has been found along the entire eastern coastal region of Australia from Cairns, Queensland, to Gippsland in eastern Victoria.<sup>35</sup>

Spotted fever rickettsial diseases<sup>1,2</sup>

The primary vector of *R. australis* is *Ixodes holocyclus* (the scrub tick), although there is also a single report of isolation of *R. australis* from *Ixodes tasmani*.<sup>36</sup> *I. holocyclus* is the principal man-biting tick in Australia, but it also feeds on a wide array of domestic and wild animals, many of which have been shown to have antibodies against SFG rickettsiae.<sup>35,37</sup>

The mite-borne SFG rickettsial species, *R. akari*, the cause of the human disease rickettsialpox, has been isolated only in temperate areas of the Northern Hemisphere such as the United States, Ukraine, Croatia, and Korea.<sup>38,39</sup> However, recent reports describing a case of rickettsialpox in a man from North Carolina and another in a patient from Turkey suggest that rickettsialpox may occur much more widely and in nonurban areas.<sup>40</sup>

Investigations in the tropics using contemporary tools are beginning to yield important information about rickettsial diseases in these locations. The most definitive studies, cultivation of rickettsiae from samples of human patients, have been accomplished recently for *R. africae* and *R. sibirica* (mongolotimoniae strain). Clinical studies of patients with acute febrile illness suspected to be dengue, typhoid, or malaria in whom these diagnoses have been excluded have shown by

IgM serology and immunoblotting that SFG rickettsioses are prevalent in study sites in Latin America and Africa.<sup>41-43</sup> Investigation of clinical samples by polymerase chain reaction (PCR) have identified candidate agents such as *R. felis* and *R. aeschlimannii*.<sup>44,45</sup> PCR studies of vectors in the endemic and outbreak areas have yielded similar candidate agents, but with weaker association as human pathogens.

Frequently, serosurveys of healthy subjects are undertaken with the aim of assessing the incidence of undiagnosed infections. For SFG rickettsiae, these studies are usually difficult to interpret owing to crossreactivity among SFG rickettsiae because of shared antigens such as the LPS. Conclusions that highly virulent organisms such as *R. rickettsii* are causing a high prevalence of asymptomatic infections are unlikely to be valid. Indeed the vast majority of *Rickettsia* identified in the tick populations to which the subjects are exposed (e.g., *R. montanensis*) have no evidence of pathogenicity.

SFG rickettsioses have been diagnosed serologically by neither rickettsial isolation nor PCR identification of the etiologic species of *Rickettsia* in Thailand, Hong Kong, and Sri Lanka.<sup>46-49</sup> Serosurveys have revealed significant presence of antibodies to SFG rickettsiae among persons in Taiwan,

the Philippines, Hainan Island, Indonesia, Mexico, Brazil, and many sub-Saharan African countries.<sup>50–53</sup>

## DISEASES

SFG rickettsioses vary in severity from a case-fatality rate of 23% in untreated RMSF to illness that is in some patients afebrile and never reported to be fatal (*R. slovaca*, *R. aeschlimannii*; see Table 50-1). Because of their severity and occurrence in tropical countries (RMSF and boutonneuse fever), high prevalence (African tick bite fever), and unique clinical presentation (*R. slovaca*–associated tick-borne lymphadenopathy), these entities will be described individually.

### Rocky Mountain Spotted Fever

After an incubation period of 2 to 14 (average 7) days, RMSF usually begins with fever, muscle aches, and headache.<sup>54,55</sup> Early in the course, nausea, vomiting, and abdominal pain occur frequently. Occasionally patients manifest these symptoms and abdominal tenderness leading to consideration of acute surgical abdomen and exploratory laparotomy. Rash usually appears on day 3 to 5 after onset of fever. Rocky Mountain spotless fever occurs in 10% to 15% patients. Such cases may end fatally. Rash may be absent or difficult to recognize in African-American patients. The rash classically begins on the wrists and ankles, spreads centripetally, and in 36% to 82% involves the palms and soles often late in the course; however, there is wide variability in the evolution, distribution, and appearance of skin rash in patients with RMSF. Some patients with RMSF have localized rashes on one body region or rashes that appear late in onset of illness manifesting only as small number of petechial lesions.<sup>56</sup> Skin necrosis or gangrene occurs in a small but important minority of patients—particularly those in whom diagnosis and treatment are delayed.<sup>57</sup>

Neurological complications such as meningoencephalitis, coma, and seizures may be life-threatening. CSF pleocytosis and/or elevated protein concentration may be seen in up to half of patients who undergo lumbar puncture. Focal neurologic deficits, meningismus, ataxia, photophobia, or transient deafness may also occur and lead to diagnostic confusion with other infectious diseases. Pulmonary manifestations including cough, radiographic alveolar infiltrates, interstitial pneumonia, and pleural effusions may be present in some cases. Adult respiratory distress syndrome (ARDS) may require mechanical ventilation and supplemental oxygen. In such cases, there is minimal myocardial dysfunction with noncardiogenic pulmonary edema caused by increased vascular permeability associated with intense rickettsial infection of the pulmonary microcirculation. However, the same vasculitic process may involve the heart, resulting in histologic and electrocardiographic changes typical of myocarditis or produce heart block in other patients. Thus, careful assessment of cardiac function is needed to distinguish patients with RMSF complicated by ARDS from those with heart failure due to *Rickettsia*-induced myocarditis. In severe cases, increased vascular permeability results in edema, hypovolemia, decreased glomerular filtration, and prerenal azotemia. In patients with severe hypotensive shock, oliguric acute renal failure may be associated with acute tubular necrosis. Aside from a petechial rash, severe hemorrhagic phenomena seldom occur. Similarly, despite

frequent thrombocytopenia, true disseminated intravascular coagulation is rare.<sup>58,59</sup>

### Boutonneuse Fever (Mediterranean Spotted Fever)

Boutonneuse fever differs from RMSF in a lower untreated case fatality rate (4% vs. 23%); the presence of a *tache noire* (eschar); a 1-cm focus of vascular rickettsial infection and injury leading to epidermal and dermal necrosis at the site of tick bite inoculation of rickettsiae in 72% of cases; and lower incidence of myalgia, petechiae, stupor, and cough.<sup>60</sup> Illness can be severe in patients with underlying disease such as cardiac failure or diabetes, old age, alcoholism, and glucose-6-phosphate dehydrogenase deficiency.<sup>61</sup>

### African Tick Bite Fever

African tick bite fever (ATBF) is a milder illness than RMSF, and fatalities are rare. After an incubation period of 5 to 7 days, patients with ATBF suffer abrupt onset of fever (59%–100%), nausea, fatigue, headache (62%–83%), myalgia (63%–87%), nuchal myalgia (81%), eschars (53%–100%), which are typically multiple (21%–54%), regional painful lymphadenopathy (40%–100%), rash (15%–46%) that is either maculopapular (14%–26%) or vesicular (0%–21%), and aphthous stomatitis (0%–11%).<sup>62,63</sup>

Patients from Uruguay suspected to have infection with closely related *R. parkeri* also had eschars and painful lymphadenopathy more often than rash.<sup>64</sup> The North American patient infected with *R. parkeri* suffered multiple eschars, regional lymphadenopathy, fever, headache, myalgia, and maculopapular rash.<sup>23</sup>

### Other SFG Rickettsioses

*Rickettsia slovaca* infection occurs in Europe during the cold months when *Dermacentor* ticks attach, usually to the occipital scalp, followed 7 to 9 days later by the presence of an eschar and painful regional (often cervical) lymphadenopathy, seldom accompanied by fever or rash.<sup>65</sup> The complication of prolonged alopecia at the site of the eschar (24%) and aesthenia persisting even after doxycycline treatment suggests the possibility of co-involvement of other factors or agents.

Although other SFG rickettsioses are clinically similar, it should be noted that there is growing recognition of severe cases of Japanese spotted fever, including a fatal case and patients with meningoencephalitis, multiorgan failure, and coagulopathy.<sup>66</sup> The recognized incidence of rickettsialpox has risen owing to more attention to evaluation of eschars in the wake of bioterrorist-associated cases of cutaneous anthrax. *Rickettsia sibirica* infections were diagnosed among a group of paleontologists doing field investigations in Mongolia, and human infections with a novel strain have been documented in France and Africa.<sup>67</sup>

## PATHOGENESIS AND IMMUNITY

SFG rickettsiae grow and undergo reactivation of virulence in the salivary glands of ticks and mites from which they are inoculated into the dermis of the skin during tick feeding. Presumably rickettsiae spread via lymphatic vessels to the

regional lymph nodes and subsequently hematogenously throughout the body. These obligately intracellular bacteria grow mainly in endothelial cells and to a lesser extent in macrophages. They enter the endothelium by attachment to a cell membrane protein by rickettsial OmpA and OmpB, induce cytoskeletal rearrangements resulting in phagocytosis, and rapidly lyse the phagosomal membrane, escaping into the cytosol where they replicate by binary fission.<sup>7,68–70</sup> SFG rickettsiae stimulate actin-based mobility via their protein RickA, which activates the host's Arp 2/3 complex that triggers nucleation of actin polymerization.<sup>71,72</sup> The actin tail that forms at one pole of the SFG *Rickettsia* propels it through the cytosol and via filopodia to the extracellular space or for cell-to-cell spread.

SFG rickettsiae injure endothelial cells by stimulation of their production of reactive oxygen species that damage cell membranes by lipid peroxidation.<sup>73</sup> The most important pathophysiologic effect of endothelial injury is increased vascular permeability leading to edema (see the Diseases section).<sup>74,75</sup> SFG rickettsiae manipulate the endothelial cells to serve as an efficient host for their growth by inhibiting apoptosis via activation of NF- $\kappa$ B, leading to inhibition of caspases 3, 8, and 9 and inhibition of release of cytochrome C from mitochondria.<sup>76</sup>

Immunity to SFG rickettsiae is mediated principally by T lymphocytes. Both CD4 and CD8 T lymphocytes secrete proinflammatory cytokines, especially IFN- $\gamma$ , which along with TNF- $\alpha$ , IL-1 $\beta$ , and RANTES activate endothelial cells, macrophages, and hepatocytes to kill intracellular rickettsiae via synthesis of nitric oxide and hydrogen peroxide and/or limitation of available tryptophan via its degradation by indoleamine-2,3-dioxygenase.<sup>77</sup> It is particularly noteworthy that following human infection by *R. africae*, serum levels of the immune mediators IFN- $\gamma$ , TNF- $\alpha$ , and RANTES are elevated.<sup>78</sup> CD8 lymphocytes provide a critical host defense with perforin-dependent elimination of infected cells by MHC class I-dependent cytotoxic T lymphocyte activity.<sup>79</sup> Dampening of the infection early in the course by innate immunity includes NK cell activation with secretion of IFN- $\gamma$ .<sup>80</sup> Antibodies to OmpA and OmpB, but not lipopolysaccharide, contribute to control of infection and are effective in preventing reinfection.<sup>81</sup>

## DIAGNOSIS

The clinical diagnosis of SFG rickettsiosis is often difficult. This difficulty is underscored by the fact that cases are sometimes only first suspected at autopsy even in areas where sophisticated medical care and diagnostic testing are available.<sup>82</sup> Fever, headache, and myalgias are nearly universal features of SFG rickettsial infections, but such symptoms are present in many other infectious diseases. Skin rash occurs in most but not all patients with *R. conorii*, *R. australis*, and *R. rickettsii* infection, but occurs in only half of patients with *R. africae* infection. A localized necrotic skin lesion (an eschar or *tache noire*) commonly occurs at the site of rickettsial inoculation by tick bite in patients with infection caused by *R. conorii* (except in Israel), *R. australis*, *R. japonica*, *R. africae*, *R. slovaca*, *R. aeschlimannii*, and *R. honei*, and by mite bite for *R. akari*. Rarely, such eschars may occur in patients with *R. rickettsii* infection as well.<sup>83</sup> It is important to note that skin rash, eschar, and a history of tick bite may be absent or easily

overlooked in some patients with SFG rickettsial infections; thus the absence of a rash or history of tick bite should not eliminate the possibility of a rickettsial disease in a febrile patient with other compatible symptoms, signs, and laboratory abnormalities such as thrombocytopenia, mental status changes, or renal insufficiency. On the other hand, a history of a recent tick bite or tick contact can be of enormous help in diagnosing SFG rickettsioses in a patient with fever and nonspecific symptoms such as myalgias, headache, and gastrointestinal complaints. Similarly when present, an eschar is often a critical clinical diagnostic sign of SFG rickettsioses, but the presence or absence of an eschar is not in itself diagnostic of SFG rickettsiosis as similar lesions occur in scrub typhus, cutaneous anthrax, tularemia, primary syphilis, and chancroid.

The diagnosis of a SFG rickettsial infection can be established by isolation or molecular detection of the causative organism from blood or tissue and by immunohistochemical methods that visualize SFG rickettsiae in skin biopsy specimens.<sup>84–89</sup> *R. conorii* and *R. africae* have also been detected in circulating endothelial cells using immunomagnetic beads to capture the detached endothelial cells and immunocytologic techniques to demonstrate the rickettsiae.<sup>90</sup> SFG rickettsial infection can be confirmed using a variety of serologic methods.<sup>91–93</sup> Most of the standard serologic techniques, such as the microimmunofluorescent antibody test, cannot distinguish among infections with the different SFG rickettsial species. In addition, PCR technology has been used to diagnose SFG rickettsial infections, but its diagnostic sensitivity remains to be proven to be adequate, particularly early in the course of disease.<sup>94–97</sup>

Because SFG rickettsial infections often begin with nonspecific symptoms and because subsequent physical and laboratory findings such as a skin rash and thrombocytopenia are easily confused with an array of other diseases prevalent in the tropics, the clinical diagnosis of SFG rickettsial infections must rest on a synthesis of epidemiologic factors such as season of the year, possible exposure to ticks or tick-infested environments, and the clinical findings. It is difficult (and sometimes impossible) to initially distinguish SFG rickettsial infections from dengue; typhoid fever; malaria; drug reaction; and exanthematous viral infections such as measles, rubella, and arboviral and enteroviral disease. Occasionally, severe infection due to *R. rickettsii* or *R. conorii* can mimic meningococcemia, staphylococcal bacteremia, toxic shock syndrome, leptospirosis, viral hemorrhagic fever, or thrombotic thrombocytopenic purpura.

## TREATMENT AND PROGNOSIS

Two drugs are the mainstays of treatment of all SFG rickettsial diseases: tetracycline and chloramphenicol. Tetracyclines such as doxycycline are generally the preferred agents, even for young children.<sup>98</sup> Despite the fact that doxycycline is safe and appropriate as initial therapy of children with suspected RMSF (and other SFG rickettsioses), there is evidence that unfounded fears of toxicity may result in a hesitancy to use this drug as empiric therapy for RMSF. For example, fewer than 5% of children presenting to a Texas children's hospital with a suspected rickettsiosis actually received doxycycline or chloramphenicol as initial therapy.<sup>99</sup> An analysis of the outcome

of 6338 patients with RMSF reported to the Centers for Disease Control and Prevention from 1981 to 1990 suggested that older patients, those treated with chloramphenicol only, patients not receiving a tetracycline as primary therapy, and those with delay in institution of therapy greater than 5 days had higher mortality rates.<sup>100</sup> Chloramphenicol is the preferred agent for pregnant women and for persons with severe illness in whom it is difficult or impossible to distinguish between a rickettsial infection and meningococcal infection. Quinolones have been shown to have activity against SFG rickettsiae *in vitro*, and in boutonneuse fever quinolones have been shown to be as effective as doxycycline in reduction in the duration of fever and are apparently superior in the rapidity of amelioration of other symptoms.<sup>101,102</sup> Although azithromycin and clarithromycin have been shown to provide equivalent successful outcome as chloramphenicol in children with mild Mediterranean spotted fever, neither they nor fluoroquinolones can be recommended at the present time for patients with moderate or severe SFG rickettsiosis. Duration of treatment of SFG rickettsial infections has not been studied systematically in a large cohort of humans. Although treatment regimens using doxycycline to treat *R. conorii* infection for time periods as short as 1 to 2 days have been reported to be as efficacious as 10-day regimens, similar studies have not been undertaken for treatment of other SFG rickettsiae such as *R. rickettsii* and *R. australis*.<sup>103</sup> Additionally, relapse of *R. conorii* infection in children treated with short courses of doxycycline has been reported.<sup>104</sup> In light of these data, most authorities recommend that tetracycline, chloramphenicol, or ciprofloxacin be continued for 7 days or until the patient has been afebrile for at least 48 hours and is improving clinically.

## PREVENTION AND CONTROL

The tick vectors of SFG rickettsiae are widespread, and control of tick populations is generally not feasible. A vaccine is not available for any SFG rickettsia. Thus, avoidance of tick bite is the only preventive method available. Tick repellants and protective clothing reduce the risk of tick exposure, but are less acceptable to persons in a warm, humid environment. Regular inspection and removal of ticks from the body prior to inoculation of rickettsiae-infected saliva also reduces the likelihood of infection.

## Typhus Group Rickettsioses

DAVID H. WALKER  
DIDIER RAOULT

### INTRODUCTION

Murine typhus, usually misdiagnosed as another ailment, is among the most prevalent febrile illnesses occurring in the tropics.<sup>1–5</sup> Louse-borne typhus is not only one of the most devastating infections in world history but also a continuing cause of morbidity and mortality among isolated, impoverished populations in tropical locations.<sup>6</sup> Like spotted fever group rickettsiae (see Chapter 50), typhus group rickettsiae are small, obligately intracellular, gram-negative bacteria that have an arthropod host as at least a portion of their ecologic niche.

Two pathogenic *Rickettsia* species are classified in the typhus group: *R. prowazekii* (epidemic louse-borne typhus, recrudescent typhus, and flying squirrel-associated typhus) and *R. typhi* (murine typhus). Typhus infections were first described by Fracastorius in 1546 based on his observations during an epidemic in Italy in 1528. Luis de Toro described an epidemic of a previously unknown, frequently fatal, acute febrile illness among soldiers in Spain in 1557.<sup>7</sup> The disease was undoubtedly epidemic louse-borne typhus based on the appearance of a macular rash on days 4 to 7 of disease, neurologic and other characteristic signs and symptoms, winter seasonality, and even association of illness with contact with clothing of the ill. As many as half of the deaths among Napoleon's 700,000 soldiers during the Russian campaign of 1812 were caused by typhus, just one example of the tremendous effect of typhus on history. Boissier de Sauvage named the disease exanthematic typhus to distinguish it from typhoid.<sup>8</sup> Not until 1836 was the differentiation of typhus fever and typhoid fever determined by Gerhard on the basis of the intestinal lesions of typhoid fever. Typhus was proved to be transmitted by human body lice by Nicolle in 1909, for which he was awarded the Nobel Prize in 1928. That the cause was an intracellular infectious agent with bacterial morphology was demonstrated by a series of investigations building one upon another performed by Ricketts, Anderson, Goldberger, von Prowazek, da Rocha-Lima, and Wolbach between 1910 and 1922. Milder forms of typhus described by Brill in 1898 in New York among emigres from Russia and other European typhus zones and by Paullin in 1913 in Atlanta were proved during the 1930s to be recrudescent of louse-borne *R. prowazekii* infection and rat flea-transmitted *R. typhi* infection, respectively.<sup>9–14</sup>

Antibiotic-resistant *R. prowazekii* strains have been developed, and both *R. prowazekii* and *R. typhi* are aerosol-transmitted biothreats.<sup>15–17</sup>

### AGENTS

Typhus group rickettsiae have a small ( $1.1 \times 10^6$  bp) genome; a 135-kD major, immunodominant S-layer protein arranged tetragonally on the cell wall surface, peptidoglycan, and abundant lipopolysaccharide.<sup>18–22</sup> Typhus group rickettsiae are highly adapted to the intracellular environment with its high potassium content and availability of compounds such as adenosine triphosphate (ATP), amino acids, and phosphorylated sugars such as uridine diphosphoglucose for which the rickettsiae possess specific transport mechanisms to their advantage in obtaining these molecules from the host cell cytoplasm.<sup>23</sup>

The bioenergetics of typhus group rickettsiae includes the production of ATP via the tricarboxylic acid cycle, one or more electron transport systems, and five ADP/ATP translocases. Early in the infection cycle when host cytoplasmic ATP concentration is high, the ADP/ATP translocases exchange ATP of the host for ADP from the rickettsiae. Later when host cell ATP is depleted, the ADP/ATP translocases are down-regulated so as not to reverse the exchange mechanism, and citrate synthase, which is a component of the tricarboxylic acid cycle, is highly expressed.<sup>24,25</sup> Interestingly, *Rickettsia* and mitochondria diverged from a common ancestor 1.5–2 billion years ago.<sup>26</sup> The rickettsial obligately intracellular lifestyle has resulted in marked genome reduction, reflecting the loss of genes required for extracellular competition. The single circular genome contains fewer than 900 genes, numerous split genes with internal stop codons, and relics of obsolete genes. Among the 41 pseudogenes of *R. typhi* are all six cytochrome oxidase genes, which are active in *R. prowazekii*. Conversely the *metK* enzyme for synthesis of S-adenosylmethionine is inactivated by mutation in *R. prowazekii* but not in *R. typhi*. Both have S-adenosylmethionine transporters.<sup>27</sup> A unique feature of *Rickettsia* is the presence of many in-frame palindromic sequence insertions with locations compatible with normal conformation and function of the proteins.<sup>28</sup>

The rickettsial ecologic cycle involves adaptation to two very different hosts: an arthropod and a warm-blooded mammal. The availability of nutrients and oxygen and other conditions vary tremendously between them. Rickettsiae contain unusual split *spoT* genes, each component of which may be functional in the stringent response—an increase in diguanosine pentaphosphate in response to starvation in the unfed arthropod or other stress—by catabolism of the toxic molecules to the energy resource ATP.<sup>29</sup> Rickettsiae also contain a family of autotransporters and some of the type IV secretion components but lack others that are not useful in the intracellular environment.<sup>25,26</sup>

### EPIDEMIOLOGY

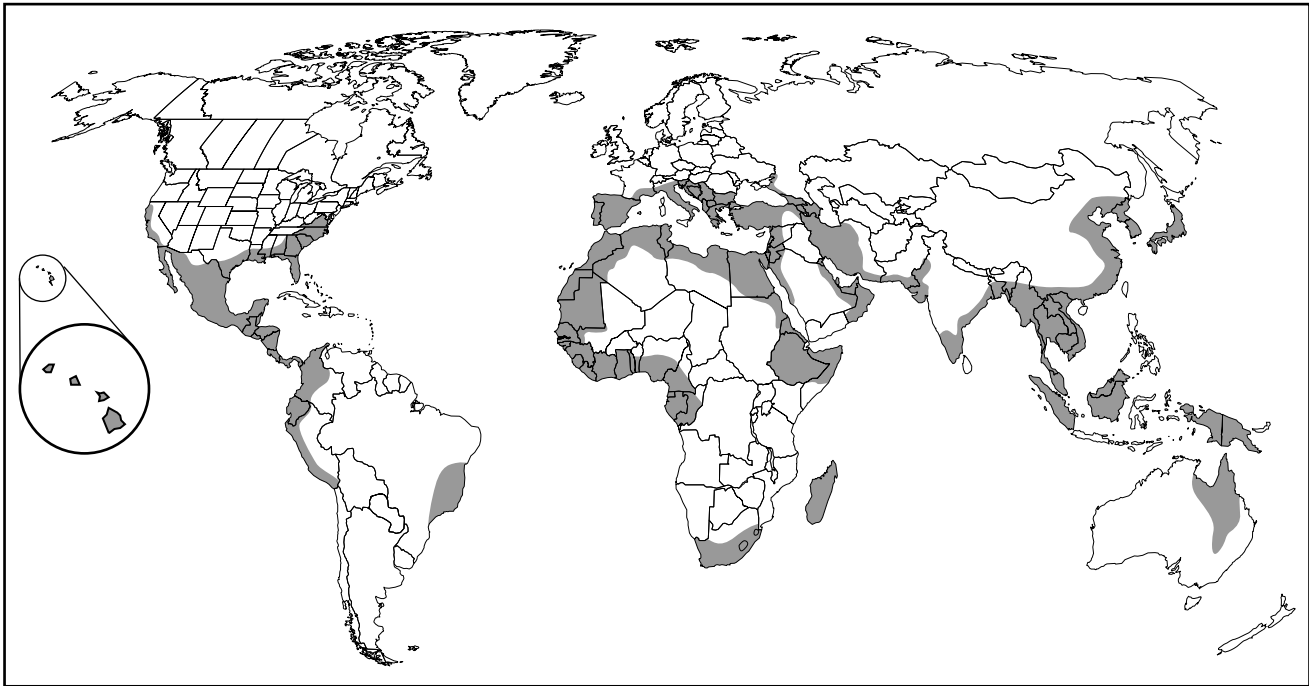

Typhus group rickettsiae that are pathogenic for humans have an insect vector (louse or flea) and are transmitted mainly in the insect's feces. *R. prowazekii* infects a high proportion of southern flying squirrels (*Glaucomys volans*) in the eastern United States and is transmitted among flying squirrels by

Epidemic (*R. prowazekii*) and murine (*R. typhi*) typhus

their own species of louse and flea without deleterious effects to the reservoir or arthropod hosts.<sup>30</sup> Human infection is likely the result of the deposition of flea feces upon humans whom the fleas will bite when the opportunity arises. The appearance of typhus fever in southern Europe during the 1500s suggests that it could have been introduced as a latent infection in a returning conquistador. Typhus was also described in Mexico nearly contemporaneously in 1545. Native Americans might have established the louse-human cycle after having become infected by contact with flying squirrels in eastern North America or Mexico. Transmission of *R. prowazekii* by human body lice (*Pediculus humanus corporis*) does not involve a high degree of adaptation of the rickettsia and the louse. Growth of rickettsiae to great quantities in the louse gut epithelium results not only in highly infectious louse feces but also in rupture of the intestine of the louse; extravasation of blood into the hemocoel, turning the louse's body red; and death of the louse.<sup>31</sup> Lice do not maintain *R. prowazekii* transovarially.

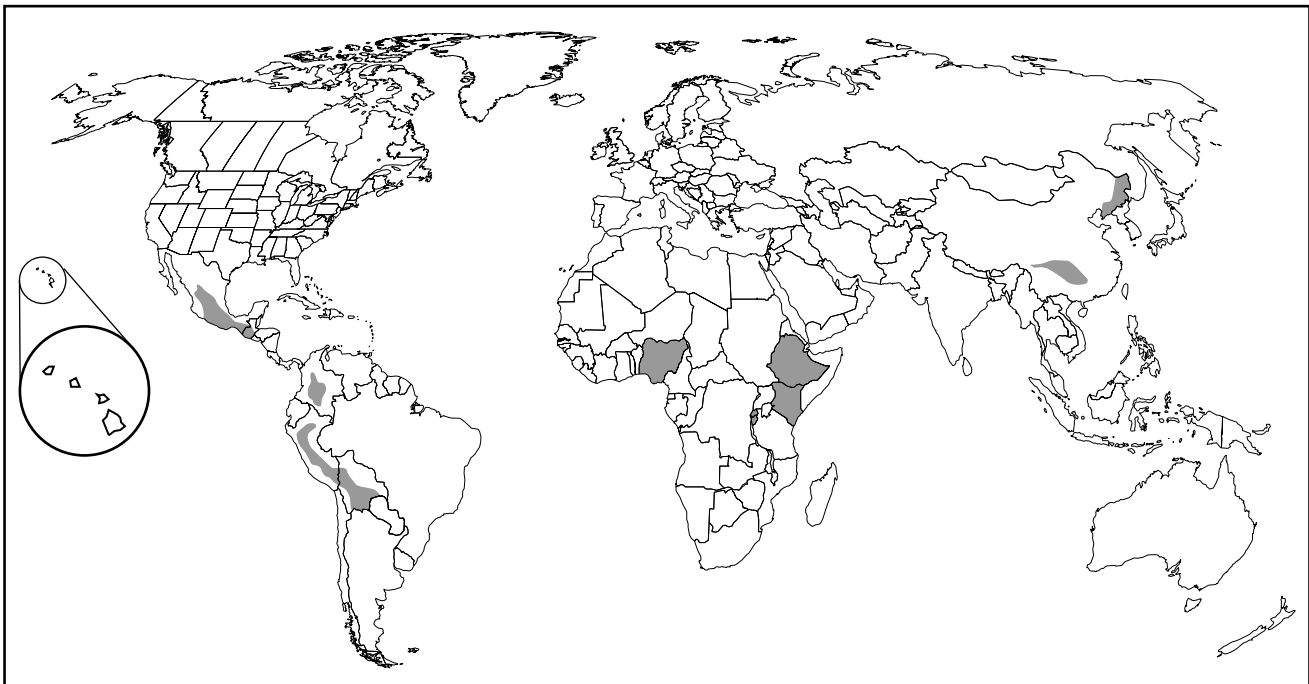

After recovery from the acute infection, *R. prowazekii* persists in many persons as an asymptomatic, latent infection. Years or decades later, presumably owing to waning immunity, the rickettsial infection reactivates as a milder, rarely fatal, bout of typhus fever with sufficient rickettsemia to infect a portion of body lice feeding on the patient. Lice do not tolerate febrile body temperatures and leave patients to seek a new host. These infected lice may transmit rickettsiae to

nonimmune subjects and ignite an epidemic under conditions of general lousiness. Recrudescent typhus usually occurs less than 10 years after acute typhus fever but may occur more than 30 years afterward. Most descriptions of louse-borne typhus are of epidemics such as occurred in Europe during and after World War I involving 30 million cases and 3 million deaths in Russia alone.<sup>32</sup> In impoverished, cold, mountainous areas such as the tropical Andes of Peru, Guatemala, Mexico, and Ethiopia and other countries in Africa and Asia, louse-borne typhus is an endemic disease.<sup>6,33-39</sup> Since the civil war in central Africa, typhus that had disappeared for 25 years reemerged in Rwanda, Burundi, and Congo and is apparently becoming endemic.<sup>34,35</sup> It has also reappeared after 30 years in Algeria and Russia, and an autochthonous case was diagnosed in a homeless person in France in 2003.<sup>36-39</sup> *Pediculus humanus corporis* lice are strictly adapted to humans and live in the clothing rather than on the body, to which they go five times a day to feed. In the endemic *R. prowazekii* situation, there are localized outbreaks of infection mainly among the young, since older persons are mostly immune and serve as the reservoir for these outbreaks when they suffer sporadic cases of recrudescent typhus. Travel and lousiness are capable of introducing *R. prowazekii* into other areas, including warm locations in the tropics where the highly susceptible nonimmune population could suffer an epidemic. Lessons learned from the epidemic of louse-borne typhus that affected between 45,000 and 100,000 patients during the civil war in Burundi are that epidemic

*Rickettsia typhi*

typhus with many fatalities can smolder in louse-infested populations of prisons and refugee camps for years without an accurate diagnosis and the disorder of war severely impedes effective epidemic control.<sup>34,40,41</sup> The occurrence of patients with evidence of latent *R. prowazekii* infection in populations where body lice are present emphasizes the need for vigilance.<sup>42</sup>

*R. typhi* occurs worldwide, particularly in warm, humid, coastal environments of the tropics and subtropics.<sup>1,3-5,43-53</sup> Prevalent in many areas although seldom investigated, murine typhus turns up frequently as recent studies in southern India, Indonesia, and Philippines have shown.<sup>54-56</sup> Among displaced Khmers at the Thai-Cambodian border, 70% of patients with

*Rickettsia prowazekii*

unexplained fever had murine typhus.<sup>4</sup> In Thailand and Laos, murine typhus is one of the most common cause of acute febrile illnesses. Although there are field and laboratory data for seven genera and 11 species of fleas, three species of lice, and three species of mites serving as vectors of *R. typhi*, the epidemiologic and ecologic evidence in most parts of the world points to the Oriental rat flea, *Xenopsylla cheopis*, as the major vector and peridomestic *Rattus* species as the critical vertebrate host. Generally rickettsiae-laden flea feces are scratched into the pruritic flea bite wound. However, a smaller fraction of infections is probably caused by flea bite. *R. typhi* might also be transmitted by rubbing infected flea feces into the conjunctival mucous membrane or by inhalation of rickettsiae from dried flea feces, in which rickettsiae have been demonstrated to survive by an unknown mechanism for years. *R. typhi* is maintained mainly by horizontal transmission from infected flea to rat to uninfected flea. Fleas remain infected for the rest of a normal life span and pass the infection transovarially to a small fraction of their offspring. Rats are highly susceptible to infection with *R. typhi*, develop sufficient ricketsemia to infect fleas imbibing their blood, and do not usually show any signs of illness. Murine typhus can spread inland along lines of transportation wherever *Rattus*, *X. cheopis*, and *R. typhi* are carried. Spread of inland foci occurred in the United States in the 1930s and 1940s.<sup>57,58</sup> Subsequent to the severe diminution in the incidence of murine typhus associated with DDT dusting and rat control, murine typhus has persisted in southern Texas and southern California, apparently in the absence of rat fleas. Cat fleas, *Ctenocephalides felis*, are the vector, and opossums are a vertebrate host of the rickettsiae and possibly serve as a reservoir.<sup>59–61</sup> Cycles involving other fleas and mammals such as in *Monopsyllus sciurorum sciurorum* fleas and the European fat dormouse might be present but as yet undetected elsewhere, including the tropics.<sup>62</sup>

Although in some instances history of exposure to rat- and rat flea-infested environments can be obtained from the patient, usually the murine typhus patient is not aware of exposure.<sup>52,63,64</sup> Flea bite is seldom recalled. A substantial proportion of patients are food handlers or are exposed to a focus with infected rats and rat fleas at work or home, usually unknowingly.<sup>57</sup>

## DISEASES

The typhus fevers have clinical similarities with differences in severity according to host factors and the greater virulence of *R. prowazekii*.<sup>65,66</sup> Contemporary series describe the diseases when ameliorated by antirickettsial treatment.<sup>46,52,63</sup> Recrudescence typhus is milder, presumably because of the stimulation of anamnestic immunity. It is not clear whether flying squirrel-associated typhus is apparently milder because of the general prior good health, nutrition, living conditions, and medical care of the patients as compared with poor, malnourished, neglected cases of louse-borne typhus or whether the eastern United States flying squirrel strains are less virulent.<sup>67–70</sup> Murine typhus is substantially less severe than louse-borne typhus, even though among hospitalized patients 10% are admitted to the intensive care unit and 1% to 4% die.<sup>63,64,71</sup>

A contemporary series of 60 patients with epidemic typhus in Ethiopia was characterized clinically by fever and headache (100%), chills (82%), rash (recognized only in 38% of these patients with pigmented skin), conjunctivitis (53%), muscle

tenderness (70%), nausea (32%), vomiting (10%), abdominal pain (30%), jaundice (17%), cough (38%), photophobia (33%), and no fatalities.<sup>6</sup> Laboratory evaluation demonstrated mild, normocytic, normochromic anemia (48%); thrombocytopenia (43%); mildly elevated serum aspartate transaminase (63%), alanine transaminase (35%), serum bilirubin (20%), lactate dehydrogenase (82%), creatine kinase (31%), blood urea nitrogen (31%), and creatinine (2%); and mild hypoproteinemia (38%). In the preantibiotic era, the fatality rate of epidemic typhus was usually at least 10% and as high as 60% under some circumstances. In the Polish series studied by Wolbach following World War I, there was a prodrome of 1 day or longer in 88%; onset characterized by fever (100%), headache (89%), chills (74%), and myalgias (54%); and admission physical examination revealing rash (100%), conjunctival injection (87%), and rales (74%).<sup>72</sup> Rash appeared on day 5 as pink 2- to 6-mm macules, usually on the trunk, followed by appearance on the extremities with usual sparing of face, palms, and soles. During the course, marked delirium (48%), coma (6%), hemorrhagic rash (34%), gangrene (4%), and opportunistic bronchopneumonia (10%) occurred, and 13.3% of patients died. The patients of the Burundi epidemic suffered from prominent myalgia as well as fever, delirium, stupor, confusion, dry cough, conjunctivitis, and the frequently prominent feature of constipation. Even in the darkly pigmented patients, a rash was often visible in the axilla (Fig. 51-1).<sup>34,40</sup> Chest roentgenograms frequently reveal interstitial pneumonia. Flying squirrel-associated typhus has been characterized by fever (100%),

**FIGURE 51-1** Rash of louse-borne typhus in a patient during the epidemic in Burundi.

headache (81%), maculopapular rash (66%), confusion (44%), and myalgia (42%).<sup>69</sup> Patients with Brill-Zinsser recrudescent typhus suffer fever, intense headache, myalgia, nausea, dulled sensorium, congested conjunctiva, constipation, and maculopapular rash appearing on the back and abdomen on days 5–7 and spreading rapidly.

In contemporary murine typhus series from Thailand, southern Texas, and Greece, after an incubation period of 1–2 weeks the clinical manifestations have been fever (98% to 100%), headache (42% to 100%, occurring less frequently in children), chills (64% to 92%), rash (2% to 71% with recognition dependent largely on darkness of skin pigmentation), myalgia (45% to 71%), nausea (31% to 59%), vomiting (23% to 40%), diarrhea (5% to 26%), abdominal pain (11% to 31%), jaundice (3% to 11%), confusion (2% to 8%), and seizures (2% to 4%).<sup>4,5,46,52,63</sup> The rash is macular or maculopapular (78%) and is petechial in less than 10%.<sup>46</sup> Murine typhus in pediatric patients is frequently mild, with half of the Thai patients suffering only nocturnal fever with normal daytime activities.<sup>73</sup> Experiments in human volunteers in the preantibiotic era documented an incubation period of 8 to 16 days (mean, 11.1 days), a prodrome usually of 2 days' duration, rash appearing in 79% of patients usually after 4 days of illness, and an average duration of fever of 12 days.<sup>74</sup> A series of 30 hospitalized pediatric cases of murine typhus had more clinical and laboratory manifestations: fever (100%), rash (80%), headache (77%), abdominal pain (60%), vomiting (43%), cough (40%), thrombocytopenia (60%), hyponatremia (66%), and hypoalbuminemia (46%).<sup>75</sup> In some patients, the signs, symptoms, and cerebrospinal fluid (CSF) mononuclear cell–predominant pleocytosis and increased protein concentration are similar to the findings in viral and leptospiral meningoencephalitis.<sup>76</sup> On the other hand, central nervous system (CNS) abnormalities may occur in patients with normal CSF. Chest radiographs are abnormal in 20% or more of patients, who have pulmonary infiltrates, atelectasis, pulmonary edema, or pleural effusions.<sup>63</sup> Laboratory evaluation of the pathophysiology reveals thrombocytopenia (48%); hyponatremia (60%); hypocalcemia (79%); elevated serum urea (27%) and creatinine (21%); hypoalbuminemia (89%); and elevated serum aspartate transaminase (90%), alanine transaminase (73%), alkaline phosphatase (60%), lactate dehydrogenase (87%), and creatine kinase (21%).<sup>63</sup> Complications may include acute renal failure (usually prerenal azotemia), respiratory failure requiring intubation, severe CNS disease, hematemesis, intracerebral hemorrhage, cardiac conduction abnormalities, intravascular hemolysis due in some cases to glucose-6-phosphate dehydrogenase deficiency or hemoglobinopathy, and exploratory laparotomy for suspected acute surgical abdomen.<sup>46,52,63,76,77</sup>

## **PATHOGENESIS AND IMMUNITY**

Typhus group rickettsiae attach to the surface of endothelial cells, rapidly stimulate their entry by induced phagocytosis, and quickly escape from the phagosome into the cytosol, where they divide rather slowly (every 8 to 10 hours) by binary fission.<sup>78</sup> Only after the endothelial cell is greatly distended with rickettsiae does it burst, resulting in its death and release of the organisms for another cycle of infection. The macrophage is a target cell for a smaller fraction of the rickettsiae. Injury to

the infected endothelium results in vascular lesions in the skin, brain, and other organs manifested as rash, encephalitis, myositis, and increased vascular permeability.<sup>72,79</sup> The last results in edema, hypovolemia, hypotension, hypoalbuminemia, azotemia, and hyponatremia. Only a very small portion of infected, injured blood vessels thrombose, and ischemic necrosis occurs only rarely.<sup>72</sup> Typhus rickettsiae have phospholipase activity that is hypothesized to play a role in entry, escape from the phagosome, and cell injury.<sup>80</sup> Analysis of the genomes of *R. prowazekii* and *R. typhi* has revealed several candidates for membranolytic function including *tlyA*, *tlyC*, *pldA*, and a gene with similarity to the patatin protein family, the main storage protein of potatoes, which also has phospholipase A activity.<sup>25,26</sup> Current evidence is strongest for expression and activity of phospholipase D (*pldA*) and typhus hemolysin C (*tlyC*).<sup>81,82</sup> Another potential virulence factor is *sodB*, an ortholog of an iron-associated superoxide dismutase, which is predicted to remove reactive oxygen species and favor rickettsial intracellular survival.<sup>25</sup> In vitro data suggest that rickettsial infection of endothelium and macrophages stimulates secretion of prostaglandin E<sub>2</sub>, prostaglandin I<sub>2</sub>, leukotriene B<sub>4</sub>, and platelet-activating factor, which along with interleukin-1 (IL-1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and other cytokines has been hypothesized to account for some of the pathophysiologic effects of typhus.<sup>83–85</sup> It is unclear whether the concentrations and locations of secretion of these mediators are likely to account in part for aspects of the disease not caused directly by rickettsial killing of endothelial cells.

Typhus lesions are composed of small blood vessels with swollen endothelium and perivascular accumulation of lymphocytes and macrophages.<sup>72</sup> Intradermal rickettsial inoculation is accompanied by prompt recruitment of perivascular infiltration of CD8 and CD4 T lymphocytes in immune humans.<sup>86</sup> Typhus rickettsiae are killed intracellularly and extracellularly by nitric oxide synthesized by murine macrophages, and potentially and more importantly by endothelial cells, activated by IFN- $\gamma$  and TNF- $\alpha$ .<sup>87,88</sup> IFN- $\gamma$  and CD8 T lymphocytes are critical effectors of immune clearance of *R. typhi* in vivo in mice.<sup>89</sup> Cytotoxic T lymphocytes recognize typhus rickettsial antigens on infected major histocompatibility antigen-matched cells.<sup>90</sup> Protective immunity appears to be mediated mainly by cellular mechanisms of adaptive immunity, but natural immunity and antibodies are likely to contribute as well.<sup>91</sup> *R. prowazekii* resides in a latent state in the lymph nodes of healthy persons long after recovery from acute typhus fever, but the mechanism of reactivation of *R. prowazekii* is poorly understood.<sup>92</sup>

## **DIAGNOSIS**

The nonspecific flulike symptoms of typhus fevers prior to the appearance of the exanthem, which never occurs in many patients, particularly the dark-skinned populations of the tropics, are nearly impossible to recognize as louse-borne typhus or murine typhus.<sup>4,6,63</sup> Typhus was confounded historically with malaria and typhoid and is frequently misdiagnosed as these two diseases currently.<sup>34,39,40,110</sup>

Prominent cough and pulmonary signs may suggest pneumonia or bronchitis; neurologic signs with or without CSF abnormalities raise the diagnostic consideration of viral or bacterial meningoencephalitis; gastrointestinal symptoms and

abdominal tenderness may suggest viral and bacterial enterocolitis or acute surgical abdomen; elevated hepatic enzymes or jaundice suggests the possibility of viral hepatitis. In addition, the differential diagnosis includes typhoid fever; malaria; leptospirosis; arboviral, enteroviral, filoviral, and arenaviral infections; meningococcemia; measles; secondary syphilis; and toxic shock syndrome. The clinical response of typhus group rickettsioses to treatment with chloramphenicol is often interpreted erroneously as support for a diagnosis of typhoid fever. Even in areas where typhus infections are well known to the medical community, the initial correct clinical diagnosis of typhus is made in only 5% to 10% of cases.<sup>63</sup> The Burundi epidemic of typhus, after years of smoldering activity, was recognized only by the investigation of the death of an emergently repatriated Swiss nurse. Murine typhus is among the most prevalent febrile illnesses in the tropics but usually remains misdiagnosed in those seeking medical attention and undiagnosed in those who have no access to health care. Typhus group infections also occur in travelers returning from endemic areas including southern Europe and southeast Asia.<sup>93–96</sup>

Often the first clue to the occurrence of a typhus group infection is a serologic result, even the least sensitive and least specific of which are not necessarily available in many tropical locations. Although the serologic diagnosis of rickettsial diseases is generally retrospective, the relatively long incubation period and lateness in the course when typhus infection is usually considered allows time for the generation of the detectable antibody response in the first serum sample of some patients.<sup>97</sup> The extensive cross-reactivity among typhus group rickettsiae permits use of any one of them as a test antigen, but does not allow easy demonstration of which agent stimulated the antibody response, since fewer than half of patients with epidemic typhus have a fourfold higher titer against *R. prowazekii* than against *R. typhi*. Cross-absorption, although capable of specific diagnosis, is laborious, expensive, and seldom undertaken.<sup>98</sup> The accepted standard is the indirect immunofluorescent antibody assay (IFA), which requires an ultraviolet microscope that seldom is available in the tropical setting.<sup>99</sup> An IgG titer of 128 or an IgM titer of 32 is considered to be diagnostic. Serodiagnosis can be achieved from blood spotted onto filter paper and mailed to a reference laboratory.<sup>100</sup> The indirect immunoperoxidase antibody assay requires only a light microscope and performs with equivalent sensitivity and specificity to the IFA.<sup>4,5,52</sup> In Thailand, the diagnostic criterion for this test in murine typhus is a fourfold or greater rise in titer to at least 200 or a single titer of either 400 or 800, depending on the serologic titers in the healthy local population. Comparison of a rapid, simple dot ELISA with IFA and the historic, but now archaic, Weil-Felix *Proteus* agglutination test demonstrated that the sensitivity and specificity of the dot ELISA were 89% and 98%, respectively, and of the *Proteus* OX-19 agglutination, 72% and 98%, respectively, at a cut-off titer of 320.<sup>97,101</sup> In certain settings, even *Proteus* OX-19 agglutination is a useful tool in recognizing the occurrence of typhus fevers. Whether or not patients with recrudescence typhus produce IgM antibodies to *R. prowazekii*, among which are those that cross-react with and agglutinate *Proteus* OX-19, is controversial.<sup>102</sup>

Immunohistologic demonstration of typhus group rickettsiae in a cutaneous biopsy or necropsy tissues also establishes the diagnosis of a typhus group infection.<sup>79,103,104</sup> An etiologic diagnosis of a specific *Rickettsia* species infection requires

isolation and identification of the obligate intracellular organisms in living cells of cell culture (most effectively the shell vial centrifugation-enhanced system), inoculated animals, or embryonated eggs, or polymerase chain reaction (PCR) amplification of DNA of a rickettsial gene and species identification by restriction fragment length polymorphism analysis or sequencing.<sup>105–108</sup> While these methods are not routinely available owing to cost and the paucity of scientists with expertise in rickettsiology, their application on a selective basis to establish the presence of the various typhus fevers in a particular region would stimulate awareness of the presence of these infections. *Rickettsia prowazekii* can be detected by PCR on lice removed from patients even after sent via mail to a reference laboratory.<sup>109</sup> Ultimately, timely presumptive diagnosis of the individual patient relies on knowledgeable clinical suspicion, and implementation of public health measures to control epidemic typhus or rats and rat fleas depends on a precise diagnosis. A bioterrorism attack of aerosol-transmitted typhus would be very unlikely to be considered diagnostically before the onset of rash, possibly not even then.<sup>17</sup>

## TREATMENT

Patients with typhus infections treated before severe hypotension, acute renal or respiratory failure, severe CNS disease, or other complications occur usually respond dramatically to antirickettsial therapy, particularly doxycycline, with defervescence within 48 to 72 hours.<sup>46,52,63</sup> Louse-borne typhus fever has been treated successfully in some settings with a single 200-mg oral dose of doxycycline.<sup>34</sup> Single-dose doxycycline treatment has greater than 80% efficacy in murine typhus but is not recommended because relapses may occur.<sup>52</sup> The current recommendations are to treat with oral doxycycline (100 mg twice daily), oral tetracycline (25 to 50 mg/kg/d in four divided doses), or chloramphenicol (60 to 75 mg/kg/d in four divided doses). Patients who are comatose or vomiting can be treated intravenously, and doxycycline or chloramphenicol is recommended for patients with renal failure. Pregnant patients should be evaluated individually and treated with either chloramphenicol (early trimester) or doxycycline (late trimester) if necessary. Treatment should, if possible, be continued for 2 to 3 days after defervescence to avoid relapse. The fluoroquinolone ciprofloxacin has been associated with treatment failure and should not be used.<sup>39,107,110,111</sup> Clinical experience, the intracellular niche, and the presence of  $\beta$ -lactamase and several multidrug transport analogs in the genomes emphasize the natural resistance of *R. prowazekii* and *R. typhi* to most classes of antibiotics.<sup>25,26</sup> The lack of therapeutic response of the 63% of pediatric patients with murine typhus to treatment with a third-generation cephalosporin is a typical situation;<sup>75</sup> in louse-borne typhus, the outcome can be fatal.<sup>110</sup> It is advisable to avoid giving sulfa-containing antimicrobials to patients suspected of having a typhus infection because these drugs actually exacerbate the disease. Strains of *R. prowazekii* resistant to chloramphenicol<sup>15</sup> or tetracycline have been selected in the laboratory, and transformation to antimicrobial resistance has been performed by molecular methods.<sup>112</sup> Thus, the specter of a bioterrorism attack with *R. prowazekii* or *R. typhi* resistant to all antibiotics is a threat that has not been addressed. Supportive care, including intensive care nursing, avoidance of pressure sores, dialysis, mechanical ventilation

with supplemental oxygen, transfusions, amputation of gangrenous extremities, and antimicrobial treatment of opportunistic pneumonia may be required in some severely ill patients.

## PREVENTION AND CONTROL

Control of epidemic and highly prevalent endemic typhus fevers depends on marked reduction in the vector and, in some cases, the reservoir populations. Murine typhus decreased from more than 5000 cases reported annually in the southern United States during the 1940s to fewer than 100 annual cases currently following repeated dusting of rat passageways with DDT, killing rats, and modifying buildings to prevent entry of rats. Epidemics of human louse-borne typhus have been curtailed by use of insecticides such as lindane powder for delousing, and washing clothes in hot water to kill the lice. Dusting powder containing 1% permethrin applied in doses of 30 to 50 mg per adult on both inside and outside of clothing and on bedding can be repeated at 6-week intervals to kill lice. Some louse populations are resistant to some of insecticides.<sup>113</sup> The large Burundi epidemic was controlled by immediate treatment of patients with 200 mg of doxycycline.<sup>34</sup> Vaccination has been used with some apparent success to prevent louse-borne typhus.<sup>113</sup> Killed *R. prowazekii* vaccines required boosters and seemed to reduce the severity of illness in persons whose protection was only partial. A live attenuated strain was used as an effective vaccine under epidemiologic conditions where dose-dependent local and systemic reactions during the 2- to 3-day period after immunization, mild to moderate symptomatic infection 9 to 14 days after inoculation in approximately 14% of recipients, and the possibility of reversion to virulence were acceptable. Use of such vaccines may be no more than a theoretical possibility at present because none are licensed or produced. Development of a highly effective, safe vaccine that would provide protection against all rickettsial infections is a feasible goal.<sup>114</sup> However, the lack of awareness of the true disease burden of these infections by public health agencies and the unlikelihood of commercial profit to be gained from the perceived target populations of the neglected poor in the tropics mitigate against vaccine development.

# Scrub Typhus

GEORGE WATT  
DAVID H. WALKER

## INTRODUCTION

Scrub typhus is a chigger-borne zoonosis which is of greatest public health importance in tropical Asia and the islands of the western Pacific Ocean. The clinical disease and vector mite were described in China in AD 313; the epidemiology and clinical course were recounted in a Chinese poem of AD 610.<sup>1</sup> The causative organism was discovered in Japan by studies of Nagayo and Ogata and their coworkers in the 1920s and early 1930s. By 1935, scrub typhus had been recognized in India, Sumatra (Indonesia), Formosa (Taiwan), the Philippines, northern Australia, the former Indochina (Vietnam), Malaya (Malaysia), Burma (now Myanmar), and New Guinea.<sup>2</sup> Scrub typhus became known to the West during World War II when an estimated 18,000 cases occurred in Allied soldiers; there were 30,000 cases in Japanese troops.

## AGENT

In 1924, Nagayo and colleagues<sup>3</sup> observed stained intracellular organisms in macrophages from tissue smears of humans and animals, but were unable to cultivate the microbes that did not pass through bacterial filters. In 1930, Nagayo and coworkers isolated and passaged the microorganisms in Descemet's membrane by inoculation of the anterior chamber of the rabbit eye.<sup>4</sup> One year earlier, in 1929, Ogata and Unro<sup>5</sup> propagated the organism through 80 passages in rabbit testis and observed them stained in macrophages, and in 1932 Ogata and associates<sup>6</sup> developed intraperitoneal infection of mice as a valuable method of rickettsial isolation.

Although the organisms meet the general definition of rickettsiae (small [ $0.5 \times 1.2$  to  $3.0 \mu\text{m}$ ], obligate intracellular, arthropod-borne bacteria), they have been reclassified into a separate genus, *Orientia*.<sup>7</sup> By 16S ribosomal RNA (rRNA) phylogeny, they are closely related (98.5% to 99.9%) to one another and substantially less closely related (90.2% to 90.6% homology) to organisms of the genus *Rickettsia*. Their cell wall differs strikingly from that of *Rickettsia* ultrastructurally, in its unique component proteins, and in the lack of lipopolysaccharide and peptidoglycan.<sup>7-11</sup> The 56-kD outer envelope protein comprises 20% of the cellular protein and has alternating hydrophobic and hydrophilic regions consistent with a transmembrane protein containing four hydrophilic variable domains of 16 to 40 amino acids of varying sequences with epitopes that are strain-specific and others that are shared with some or all strains. There is 59% to 82% overall amino acid homology among the various strains.<sup>9</sup> The antigenic and

genetic diversity of this major outer membrane protein is vastly different than in the classic Kato, Karp, and Gilliam strains. Other major surface-exposed proteins are 110, 47, and 25 kD in molecular mass and also manifest antigenic diversity.<sup>12,13</sup>

Heat shock proteins of 58 to 60 kD and 11 kD, analogues of GroEL and GroES, have species-specific DNA sequences.<sup>14</sup> Genetic analysis of 111 strains of *O. tsutsugamushi* from Thailand based on restriction patterns of the products of polymerase chain reaction (PCR) amplification of the 58- to 60-kD heat shock protein showed 35 *groE* genotypes.<sup>15</sup> Each geographic area had its own particular genotypes that were highly restricted to specific localities with little spread. Isolates from other countries also showed considerable variability that was unique to each country. Despite the enormous genetic and antigenic variability, the organism seems genetically stable; the 22- and 56-kD protein genes of rickettsiae from isolates from a chigger colony obtained 26 years apart were identical. These data suggest a large number of isolated, independent chigger lineages of *O. tsutsugamushi* with a long history of divergent evolution.

## EPIDEMIOLOGY

The disease or its etiologic agent has been documented within a triangle with apices in the Primorje region of the Russian Far East, northern Australia, and Afghanistan.

Endemic areas range from typical tropical secondary growth (scrub) vegetation to temperate zones (e.g., Kashmir, Korea, and Mount Fuji) and even the Himalayas above 3000 m elevation.<sup>2,16,17</sup> The ecologic factors underlying the reemergence of scrub typhus that has been documented recently in southern India, Sri Lanka, and the Maldives are not known.<sup>18,19</sup> Active rice fields appear to be an important underappreciated ecological niche of transmission, and agricultural exposure including on oil palm and rubber plantations and forestry poses a major risk. The etiologic agent, *O. tsutsugamushi*, is maintained by efficient transovarial transmission in trombiculid mites and is transmitted to humans by the larval mite (chigger) during feeding.<sup>20,21</sup> Only the six-legged larva is parasitic, feeding for 2 to 10 days on the tissue juices of the skin. The eight-legged nymphs and adults are predators that live in the forest floor. The chiggers are not host-specific, and wild rats are susceptible to long-lasting infections. The rats are key to the population density of the chiggers but are not a reservoir of *O. tsutsugamushi*; only a low proportion of chiggers acquire *O. tsutsugamushi* from infected rats, and chiggers infected by feeding neither develop a generalized infection nor transmit the organisms transovarially to their offspring.<sup>16</sup>

Transmission to humans occurs during the seasonal activity of the chigger, which is determined by temperature and humidity: *Leptotrombidium akamushi* transmission occurred in Japan during July to September when the temperature is above 25°C but seems to have disappeared; *Leptotrombidium pallidum* transmission occurs in Japan, Korea, and the Primorje region of Russia in two peaks, autumn to winter and late spring to early summer at 18°C to 20°C; *Leptotrombidium scutellare* transmission occurs in Japan, China, and Malaysia only in autumn and winter at 18°C to 20°C; and transmission by *Leptotrombidium deliense*, *Leptotrombidium fletcheri*, and *Leptotrombidium arenicola* occurs in warm, humid tropical areas year-round.<sup>2</sup> The efficiency of transovarian transmission varies from mite to mite and temporally in individual mites.<sup>22,23</sup> Infection of female mites results not only in transovarial maintenance of *Orientia* but also in sex ratio distortion in favor of females, further enhancing transovarian transmission.<sup>24</sup>

Disease transmission occurs in rural and suburban areas as well as in villages, but inhabitants of city centers are not at risk. Most cases go undiagnosed because symptoms and signs are often nonspecific and commercial diagnostic tests are generally not available. Where prospective, longitudinal studies have been performed, as in peninsular Malaysia, a high incidence has been observed. Scrub typhus was the cause of 18.3% and 23.3% of febrile admissions at two hospitals.<sup>25</sup> In two communities the incidence of *O. tsutsugamushi* was 3.9% and 3.2% per month; the seroprevalence was 48% and 53% with an age-dependent increase to greater than 80% above age 44 years.<sup>26</sup> Exposure to remote scrub and forested areas of Laos, Vietnam, and Cambodia resulted in seroconversion at a rate of 484 per 1000 person-years.<sup>27</sup> It appears that pathogenicity is age-dependent and varies geographically. In the preantibiotic era, the case-fatality rate in Japan was 30% (15% in 11- to 20-year-olds, 20% in 21- to 30-year-olds, and 59% in those above age 60 years).<sup>28</sup> In Taiwan the case-fatality rate was 11% (5% in children and 45% in the elderly). In the Pescadores Islands, the case-fatality rate was only 3%. Among Allied troops during World War II, outbreaks were usually associated with the early stage of development of

a camp when chiggers were plentiful, with case-fatality rates ranging from less than 1% to more than 30%.<sup>29</sup>

## DISEASE

The chigger bite can occur on any part of the body, is painless, and is not usually remembered by the patient.<sup>30</sup> An eschar forms at the bite site in about half of primary infections and a third of secondary infections. The eschar begins as a small, painless papule and develops during the 6- to 20-day (average 10-day) incubation period. It enlarges, undergoes central necrosis, and acquires a blackened scab (Plate 52-1). The eschar is usually well developed by the time fever appears. Regional lymph nodes are enlarged and sometimes tender. Fever and headache begin abruptly and are frequently accompanied by myalgias and malaise. Hearing loss concurrent with fever occurs in about one-third of cases and is a very useful diagnostic clue.<sup>31</sup> Conjunctival hyperemia and generalized lymphadenopathy are frequently occurring, diagnostically helpful physical signs.<sup>32</sup> A transient macular rash may appear at the end of the first week of illness. The rash appears on the trunk, becomes maculopapular, and spreads peripherally. However, it is often difficult to detect on dark-skinned persons. The systemic involvement was demonstrated by gastric endoscopic observations that paralleled the cutaneous manifestations in the 23% of scrub typhus patients who had gastrointestinal symptoms.<sup>33</sup> The vascular pathology and pathophysiology are emphasized in the report of a scrub typhus patient with retinal hemorrhages and increased vascular permeability observed by fluorescein retinal angiography.<sup>34</sup>

Cough, tachypnea, and infiltrates on chest radiography are among the most frequent presentations of scrub typhus.<sup>35</sup> Tachypnea sometimes progresses to dyspnea, the patient becomes cyanotic, and full-blown adult respiratory distress syndrome (ARDS) may ensue. ARDS is associated with older age and preceding infiltrates on chest radiographs in patients with scrub typhus who have a higher risk of dying, but if they recover, have no serious sequelae.<sup>36</sup> Relative bradycardia is the main cardiac manifestation.<sup>37,38</sup> Confusion, apathy, and other mild personality changes are common. Convulsions and coma occur only rarely.<sup>39</sup> In a patient with severe encephalomyelitis, MRI lesions were observed in locations corresponding to the neurologic deficits and the usual distribution of pathologic lesions.<sup>40</sup> Severe disease associated with delayed diagnosis may be associated with ARDS, acute renal failure, hypotensive shock, and occasionally disseminated intravascular coagulation.

## PATHOGENESIS AND IMMUNITY

Human volunteers fed upon by infected chiggers developed a febrile illness with an eschar and regional lymphadenopathy after an 8- to 10-day incubation period during which organisms were apparently inoculated from the salivary glands of the chiggers into the dermis and subsequently spread to the regional lymph nodes and bloodstream.<sup>21</sup> Bacteremia was detected 1 to 3 days before onset of fever.

The target cells of *O. tsutsugamushi* in humans are endothelial cells throughout the body, macrophages, and cardiac myocytes.<sup>41,42</sup> Organisms have been identified in pleural, pericardial, and peritoneal cells in spleen and liver, and mononuclear cells circulating in the blood.

Evaluation of the results of both experimental animal infections and studies in cell culture is confounded by the unclear relevance of the target cells in these models. In mice, the route of inoculation determines the distribution of rickettsiae: peritoneal serosa, exudate, and adjacent organ capsules after intraperitoneal inoculation; macrophages, including Kupffer cells, splenic sinusoid–lining cells, lymph node sinus–lining cells, and interstitial cells of the lung, kidney, and adrenal with subcutaneous or intramuscular inoculation; and meningeal cells following intracerebral inoculation.<sup>43</sup> The apparent lack of significant endothelial cell infection in these models renders interpretation of their relevance problematic.

The basic histopathologic lesions, disseminated perivascularitis, and focal interstitial mononuclear infiltrations associated with edema appear to reflect the host response to endothelial infection.<sup>44</sup> Thrombotic lesions are rare.<sup>42</sup> The most important lesions are interstitial pneumonia with alveolar edema, hemorrhage, occasionally hyaline membranes, interlobular septal edema, and meningoencephalitis.<sup>41,42,44,45</sup> Correspondingly, the causes of death are respiratory failure, central nervous system (CNS) involvement with coma, and peripheral vascular collapse.<sup>41</sup> Other lesions include pleural effusions, splenomegaly, erythrophagocytosis, and leukophagocytosis in the spleen, liver, and lymph nodes; bone marrow hyperplasia; multifocal interstitial nephritis; and interstitial and perivascular myocarditis, which is pathophysiologically insignificant.<sup>41,42,44,45</sup>

*O. tsutsugamushi* attaches to its host cell via a surface protein, enters by stimulating phagocytosis, escapes from the phagosome, and replicates by binary fission in the cytosol. Spread to infect other cells occurs via budding projections from the infected cell contacting a neighboring cell, which engulfs the host membrane–bound or free bacterium.<sup>2,46</sup> Within the new cell, the organism enters the cytosol by lysing the intervening host cell membranes.

Studies of the interaction of *O. tsutsugamushi* with endothelial cells or macrophages in cell culture have elucidated some of the fundamental pathogenesis of scrub typhus. Neutralization of *O. tsutsugamushi* infectivity by antibodies directed against epitopes of the 56-kDa major cell wall protein suggests that it plays a role in adhesion and/or entry into the host cell on which heparan sulfate glucosaminoglycan is a receptor.<sup>47</sup> *O. tsutsugamushi* are moved intracellularly to the microtubule organizing center where replication occurs.<sup>48</sup> Antibody-opsonized organisms escape from the phagosomes of polymorphonuclear leukocytes, but their intracellular movement is altered. Although orientiae can inhibit apoptosis of human macrophages by reducing intracellular release of calcium ions from endoplasmic reticulum, cells heavily infected with orientiae undergo apoptotic cell death in association with decreased expression of anti-apoptotic bcl-2, decreased actin stress fiber polymerization, and decreased cellular focal adhesion kinase and paxillin.<sup>49</sup>

Immunity to *O. tsutsugamushi* is incomplete, with frequent reinfections. Immunity to the homologous strain has been shown to last for up to 3½ years, but immunity to heterologous strains begins to wane after 1 month and is usually absent after a year, although the illness is often milder.<sup>50,51</sup> Primary infections are more often symptomatic than infections of previously immune persons.<sup>52</sup> Seroconversion has been observed in asymptomatic subjects and mildly ill patients, but whether owing to immune protective mechanisms or avirulent strains is not known.<sup>53</sup>

Experimental studies in mice have shown that T lymphocytes are critically important to immunity.<sup>54</sup> Antibodies to the homologous strain confer partial protection, but heterologous antibodies do not.<sup>55</sup> Antibodies enhance clearance of *O. tsutsugamushi* from the blood, and B-lymphocyte depletion increases the susceptibility of mice to a moderately pathogenic strain.<sup>54</sup> Whether antibodies inhibit attachment and entry or other host–*Orientia* interactions is not clear.<sup>56,57</sup> The potential importance of macrophages is suggested by the conversion of infection with a sublethal dose to a fatal infection when macrophage function is impaired by treatment with silica.<sup>58</sup>

A single gene that determines resistance or susceptibility of mice to *O. tsutsugamushi* is related to its role in generating an effective Th1-type cell-mediated immunity. Indeed, murine macrophages activated by IFN- $\gamma$  kill *O. tsutsugamushi*, and TNF- $\alpha$  inhibits the growth of orientiae in human endothelial cells.<sup>59,60</sup> The source of protective TNF- $\alpha$  is likely mononuclear phagocytes, although one study reported that *O. tsutsugamushi* infection of murine macrophages does not stimulate TNF- $\alpha$  production, which does in fact result from stimulation of immune spleen cells with *O. tsutsugamushi* antigen.<sup>61–63</sup> The observation of elevated concentrations of serum IFN- $\gamma$  and macrophage colony-stimulating factor in patients during the acute stage of scrub typhus suggests roles as host defenses.<sup>64</sup> Immune cytotoxic T lymphocytes mediate major histocompatibility complex (MHC) class I-restricted cytotoxicity against *O. tsutsugamushi*-infected target cells.<sup>65</sup> Immune mechanisms clearly do control rickettsial infection of peritoneal macrophages, resolve the hepatic lesions, and control the peritonitis in mice. Immune cytokines are likely very important in vivo with cytotoxic T lymphocytes and antibodies potentially also playing significant roles. The perivascular lymphohistiocytic infiltrate, the likely source of paracrine immune cytokines, may result from production of macrophage chemoattractant proteins 1 and 2, macrophage inflammatory proteins 1 $\alpha$ , 1 $\beta$ , and 2, and RANTES by endothelial cells and/or macrophages.<sup>63,66,67</sup>

## DIAGNOSIS

The diagnosis can be simple in a patient who has visited an endemic area and presents with a fever, rash, eschar, lymphadenopathy, and acute hearing loss. Unfortunately, this scenario is rarely the case. Scrub typhus is an often overlooked cause of both pyrexia and pneumonitis of undetermined cause.<sup>25,35</sup> The single most useful diagnostic clue is the eschar, which is virtually pathognomonic when seen by a physician experienced in diagnosing scrub typhus. However, even a typical eschar can be overlooked,<sup>68</sup> eschars without crusts are often misdiagnosed, and many cases of scrub typhus do not manifest an eschar.

Laboratory confirmation is difficult. The Weil-Felix test using the *Proteus* OX-K antigen is often the only diagnostic tool readily available in endemic areas, but it is unacceptably insensitive.<sup>32</sup> The indirect immunofluorescence and immunoperoxidase assays have been considered as the gold standard reliable serodiagnostic methods<sup>69–71</sup> but have technical requirements which limit their use to a small number of medical centers. Rapid diagnostic tests requiring no special equipment and reliable recombinant 56-kDa protein antigen tests have been developed. The best results have been obtained with a pool of truncated recombinant 56-kDa proteins of Karp, Kato,

and Gilliam strains, which has been prepared as a dipstick test on a rapid lateral flow assay for the serodiagnosis of scrub typhus in the rural tropics where the majority of disease transmission occurs.<sup>72–75</sup> The introduction of tests that do not rely upon microscopy holds great promise for improving the serodiagnosis of scrub typhus, particularly in the rural tropics. The same antigens are also very appropriate for use in enzyme immunoassays in the reference diagnostic laboratories<sup>76</sup> for accurately testing large numbers of sera.<sup>77</sup>

*O. tsutsugamushi* can be isolated from blood or tissues. Whole blood from patients with acute scrub typhus is injected intraperitoneally into white mice, which are then observed for signs of illness or death. Organisms can be demonstrated in Giemsa-stained impression smears taken from the surface of the spleen or peritoneum.

The etiologic diagnosis can also be made by performing PCR assays on whole blood or even on dried blood dotted onto filter paper.<sup>78–82</sup> However, the sensitivity and specificity of PCR for diagnosing scrub typhus have not yet been determined by prospective clinical trials. Further refinements may lead to more widespread use of PCR for diagnosis of *O. tsutsugamushi* infection, but expense and technical requirements currently constrain its use to the research setting.

The differential diagnosis depends on the diseases prevalent in the area in which the illness originated. The importance of a careful search for an eschar cannot be overemphasized—its presence is virtually pathognomonic for scrub typhus in much of Asia. Tularemia, spotted fever rickettsiosis, and anthrax can cause eschars but have a different epidemiology. Eschars frequently occur in the genital region, where they often lose their crust. Thus they can be confused with the ulcers of syphilis, chancroid, or lymphogranuloma venereum. A rash that is hemorrhagic, particularly if associated with leukopenia and thrombocytopenia, suggests infection with dengue virus rather than *O. tsutsugamushi*. Marked myalgia, liver involvement, and raised serum creatinine levels suggest leptospirosis rather than scrub typhus. However, dual infections with leptospirosis and scrub typhus have been reported.<sup>83</sup> Typhoid fever and malaria are prominent in the differential diagnosis, but plasmodia are generally detectable in blood films from Asian patients infected with *Plasmodium* spp. and enteric fever rarely causes generalized lymphadenopathy or conjunctival suffusion. Infectious mononucleosis was the most frequent misdiagnosis in American servicemen serving in Vietnam who were infected by *O. tsutsugamushi*.<sup>32</sup> Febrile patients from urban areas are more likely to have murine typhus than scrub typhus, although transmission of *O. tsutsugamushi* occurs in suburban areas of Bangkok, Hong Kong, and Canton.<sup>84,85</sup>

## TREATMENT AND PROGNOSIS

Scrub typhus is said to respond even more promptly to antibiotics than other rickettsial diseases, with patients generally becoming afebrile within 24 to 36 hours after beginning antibiotic therapy. Early antibiotic treatment shortens the disease course, reduces mortality, and accelerates convalescence. Treatment must often be presumptive, and the benefits of avoiding severe scrub typhus by early antibiotic administration generally outweigh the risks of a 1-week course of tetracycline—the treatment of choice. Either oral tetracycline (500 mg four times daily) or oral doxycycline (100 mg twice daily for 7 days)

is recommended. Shorter treatment courses are often curative, but may result in relapse.<sup>32</sup> A 1-week course of chloramphenicol (50 to 75 mg/kg/day) is also effective although less so than tetracyclines. Parenteral therapy should be given to patients who are vomiting or have severe disease. In areas where parenteral formulations of tetracyclines are unavailable, chloramphenicol is a useful alternative for treatment of severe disease.

The susceptibility of different strains of scrub typhus to antibiotics can be determined in mice, in cell culture, and by flow cytometry.<sup>86,87</sup> Scrub typhus cases from northern Thailand that respond poorly to conventional therapy have been described.<sup>88</sup> Whether resistant strains occur elsewhere is unknown. The mechanism of resistance has not yet been elucidated. Rifampin was the only antibiotic more active than doxycycline against resistant strains of *O. tsutsugamushi* in mice and was equally effective against drug-sensitive strains. Rifampin controlled fever more rapidly than did doxycycline in a controlled, blinded treatment trial of mild scrub typhus acquired in Chiangrai Province in northern Thailand.<sup>89</sup> However, neither the efficacy of rifampin for severe disease nor the optimal treatment regimen for drug-resistant scrub typhus have yet been determined. Ciprofloxacin treatment does not appear to be effective.<sup>18</sup>

Therapy for pregnant women and children poses several problems. Chloramphenicol is best avoided during pregnancy and cannot be given to neonates; tetracycline is contraindicated in pregnancy because of its teratogenic potential, and repeated long courses administered to young children cause staining of the permanent teeth. Newer macrolide antibiotics appear to be effective for scrub typhus. Roxithromycin treatment of children with scrub typhus yielded defervescence as promptly as doxycycline or chloramphenicol.<sup>90</sup> Three Japanese patients were treated successfully with clarithromycin,<sup>91</sup> and cases of both drug-sensitive and drug-resistant scrub typhus have been cured by azithromycin. Macrolides would be particularly useful for the treatment of *O. tsutsugamushi* infection during pregnancy and early childhood. The need for effective treatment in pregnant women and infants is underscored by recent documentation of transmission of scrub typhus from mother to fetus.<sup>92</sup>

Scrub typhus was a dreaded disease in the preantibiotic era. Prompt antibiotic therapy generally prevents death, but in northern Thailand up to 15% of patients still die. Deaths are attributable to a variety of factors, including late presentation, delayed diagnosis, and drug resistance. The severity of scrub typhus does not appear to be increased in patients infected with human immunodeficiency virus (HIV).<sup>93</sup> Surprisingly, HIV viral load falls in a substantial proportion of AIDS patients during acute scrub typhus.<sup>94</sup> A passive plasma transfer study showed that long-acting factors that suppress HIV appear in the blood during some acute scrub typhus infections.<sup>95</sup> It has been suggested that *O. tsutsugamushi*-related HIV suppression may be mediated by antibody or other pathways such as downregulation of the CCR5 coreceptor for HIV.<sup>61</sup> Good supportive care and early detection of complications are important in severe cases if a good outcome is to be obtained.

## PREVENTION AND CONTROL

Weekly doses of 200 mg of doxycycline can prevent *O. tsutsugamushi* infection.<sup>96,97</sup> Weekly chloramphenicol is also

effective,<sup>98</sup> but has unacceptable risks for use as chemoprophylaxis. Daily doxycycline prevents malaria, but its ability to prevent scrub typhus has not been tested; daily chloramphenicol is not protective.<sup>98</sup> Chemoprophylaxis should be considered for nonimmune persons sent to an endemic area to perform work that places them at high risk of acquiring scrub typhus. Soldiers and road construction crews are typical examples, but chemoprophylaxis should also be considered in high-risk travelers such as trekkers. Contact with chiggers can be reduced by applying repellent to the tops of boots, socks, and on the lower trousers and by not sitting or lying directly on the ground. Unfortunately, these measures are frequently not practiced by those exposed occupationally.

During the 1940s, attempts to protect man against scrub typhus by immunization with killed rickettsial vaccines gave uniformly discouraging results under the conditions of field exposure.<sup>99,100</sup> Other vaccine strategies have included gamma-irradiated organisms that were metabolically active but incapable of growth, and combined infection and antibiotic prophylaxis.<sup>51,101</sup> Currently there is no vaccine in use. The protection of mice with a recombinant 56-kD protein vaccine that stimulated both T- and B-lymphocyte responses sounds a note of encouragement,<sup>102</sup> but the existence of innumerable heterologous strains implies that a broadly effective vaccine might not be forthcoming soon.

# Ehrlichioses and Anaplasmosis

J. STEPHEN DUMLER  
DAVID H. WALKER

## INTRODUCTION

As human habitats increasingly overlap those of ticks and their hosts, exposure to previously unrecognized microbes that have evolved within mammalian–tick enzootic cycles occurs, and significant new human pathogens have emerged. Important examples of this process include obligately intracellular bacteria related to the genus *Rickettsia* that are in the family Anaplasmataceae and the genera *Ehrlichia* and *Anaplasma*.<sup>1,2</sup> *Neorickettsia* (*Ehrlichia*) *sennetsu* was identified as a cause of a mononucleosis-like illness in Japan in 1954, and since 1986, at least four new distinct species in the family Anaplasmataceae have been identified as tick-borne human pathogens.<sup>1–5</sup>

## AGENTS

Anaplasmataceae are classified based on similarities in *rrs* (16S ribosomal RNA genes), *groESL*, *rpoB*, and *gltA*. A recent reclassification resulted in the current scheme for Anaplasmataceae, including the genera *Ehrlichia*, *Anaplasma*, *Neorickettsia*, and *Wolbachia*.<sup>2,6,7</sup> *N. sennetsu* infects mostly mononuclear phagocytes, has never been identified in humans outside of the Far East, and is likely transmitted by ingestion of trematode-infested fish. *Ehrlichia chaffeensis* infects peripheral blood monocytes and tissue macrophages and is the major cause of human monocytotropic ehrlichiosis (HME) in the United States.<sup>1,5,8,9</sup> With the recent taxonomic reorganization, the former *E. phagocytophila* or human granulocytic ehrlichiosis (HGE) agent that infects neutrophils is now called *Anaplasma phagocytophilum*.<sup>2,10,11</sup> *Ehrlichia ewingii*, a pathogen of neutrophils, has also been identified as a significant human pathogen in the United States, particularly among immunocompromised patients.<sup>4,12</sup> A role for *Wolbachia* spp. that infect filarial nematodes has been proposed in complicating human filariasis based upon exacerbation of inflammation by the symbiont's components.<sup>13</sup> Finally, a single person with asymptomatic persistent *Ehrlichia canis* infection was identified in Venezuela.<sup>3</sup> It must be remembered that, until recently, Anaplasmataceae were considered only as pathogens of animals or as benign symbiotic bacteria. Moreover, a number of Anaplasmataceae cause diseases in animals in tropical locations. Given the propensity for some to infect potentially both animals and humans, it would not be surprising to discover

that previously or newly identified Anaplasmataceae beyond *Wolbachia* spp. are significant causes of human disease in tropical regions.

With the exception of *Wolbachia* spp. (which will be separately considered), each of the Anaplasmataceae pathogenic for humans lives within professional phagocytic cells in vivo in an endosome.<sup>14,15</sup> Although not proved for all species, these intracellular bacteria attach to ligands on phagocytic cells, are engulfed, and then subvert intracellular endosomal trafficking to avoid lysosomal fusion and to allow replication within the vacuole.<sup>16,17</sup> Another common theme among these organisms is the ability to generate a changing variety of surface immunogenic proteins, which probably contributes to immune evasion in persistently infected reservoir hosts but could also allow infection of new niches among alternative hosts such as humans.<sup>18–20</sup> The closely related genera *Ehrlichia* and *Anaplasma* are tick-transmitted, whereas *Neorickettsia* spp. rely on infection of trematode stages and their hosts, and *Wolbachia* symbionts of *Brugia*, *Onchocerca*, and other filarial nematodes are passed transovarially.<sup>21–24</sup> The mechanisms of cell injury are not known, although increasing data suggest the induction of immunopathologic responses such as overproduction of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ).<sup>25–27</sup>

In vitro cultivation was a major limitation in the study of *Ehrlichia* spp. and the diseases they cause. However, recent investigations have led to the development of methods for cultivation in specific host cell lines. Such developments as the growth of *Ehrlichia canis* and *E. chaffeensis* in the canine DH82 or human THP-1 macrophage cell line,<sup>9,28,29</sup> *A. phagocytophilum* in human HL-60 promyelocyte cells,<sup>30</sup> and the growth of several species in tick cell cultures<sup>31</sup> allow more comprehensive investigation and development of reproducible diagnostic tools. Remarkably, the genome sequences of *E. chaffeensis*, *E. canis*, *Ehrlichia ruminantium*, *A. phagocytophilum*, *N. sennetsu*, *Anaplasma marginale*, *Wolbachia pipientis*, and several other *Wolbachia* spp. are nearing completion and should propel fundamental and translational research on infections caused by these agents.

## ■ Human Monocytotropic Ehrlichiosis (HME)

### AGENT: EHRLICHIA CHAFFEENSIS

*E. chaffeensis* cells have a wide range of ultrastructural appearances.<sup>32</sup> In general, two types of ehrlichial cells are observed within the vacuoles of host cells: ehrlichiae with a central condensation of ribosomes and DNA fibrils, called *dense-core cells*, and ehrlichiae in which these components are evenly distributed throughout the bacterium, called *reticulate cells*. While both forms have been observed in replication, the gp120 that is implicated as an adhesin of *E. chaffeensis* is differentially expressed on dense-core cells, analogous to the situation in *Chlamydia*.<sup>33</sup>

The antigenic constituents of *E. chaffeensis* have been examined in some detail. Protein immunoblots of *E. chaffeensis* with experimentally prepared antisera and sera from convalescent human patients reveal the presence of dominant antigens at 200, 120, 66, 55, 44, 29, 28, and 22 kD.<sup>34,35</sup> However, analysis of additional isolates of *E. chaffeensis* has indicated

a degree of variation in structure and specific epitopes.<sup>36</sup> The immunodominant p28 family of proteins in *Ehrlichia* is encoded by at least 22 paralogs that are present contiguously in a locus and can be independently transcribed.<sup>37</sup> The 120-kD protein appears to function in some degree as an adhesin.<sup>33</sup> Both the 120-kD protein and another surface-exposed protein called VLPT contain variable numbers of tandem repeats.<sup>38</sup> Components of a type IV secretion mechanism expressed by *E. chaffeensis* are found in the parasitophorous vacuoles of infected macrophages.<sup>39</sup> Their presence suggests the potential for direct introduction of cell-regulating bacterial proteins and components that may directly or indirectly influence the recognized changes in host gene transcription with infection.<sup>40</sup>

## EPIDEMIOLOGY

HME was identified because of clinical and geographic similarities to Rocky Mountain spotted fever (RMSF).<sup>1,5,41</sup>

Onset is associated with tick exposure and bites, and the major vector is *Amblyomma americanum*, the Lone Star tick.<sup>1,5,21</sup> Lone Star ticks are found across areas of the south-central and southeastern United States, coinciding generally with areas where HME is found. All stages of *A. americanum* readily feed on deer, which are the major reservoir.<sup>42</sup> Deer experimentally inoculated with *E. chaffeensis* become persistently infected in the absence of disease.<sup>43</sup> White-tailed deer (*Odocoileus virginianus*) in regions of the southeastern and central United States have been reported to be infected or to have serologic evidence of infection.<sup>42</sup> White-tailed deer in areas devoid of Lone Star ticks show an absence of exposure to *E. chaffeensis* until Lone Star ticks spread into those regions and serologic evidence of infection emerges in deer.<sup>44</sup> Many canids have serologic evidence of infection with *Ehrlichia* infections, and dogs can be persistently infected subclinically with *E. chaffeensis*.<sup>45-47</sup>

The incidence and prevalence of HME are poorly documented. Prior investigations indicate that the infection

occurs at a rate similar to or greater than that of RMSF, and recent studies based upon active, prospective identification in southeastern Missouri suggest that HME occurs at least at rates of 2 to 5 per 100,000 population—figures that are 10-fold higher than reported in investigations by passive reporting and are possibly more than an order of magnitude even higher.<sup>1,5,48–50</sup> Serologic studies suggest that infection with *E. chaffeensis* or an antigenically related organism also occurs in Europe, Africa, Asia, and Latin America.<sup>3,51–55</sup> Asymptomatic seroconversion may confound seroprevalence and diagnostic studies<sup>56</sup>; moreover, milder infection with *E. ewingii* or the presence in ticks of *Ehrlichia* spp. that are nonpathogenic to humans may account for some serologic reactions in tick-exposed populations.<sup>57</sup> Most infections occur from April through September, with a peak in July, when the ticks are active.<sup>1,5</sup>

## DISEASE

Most individuals with HME have an undifferentiated febrile illness within 1 to 4 weeks after tick exposure or bite.<sup>1,5,50,58</sup> The mean age is 48 years, although infections also occur in children, for whom the age-adjusted seroprevalence in the south central and eastern United States varies between 2% and 22%.<sup>59</sup> Although most patients reside in rural areas, rural zip codes and seroprevalence are not correlated.<sup>59</sup> Frequent findings include headache, myalgias, and malaise, while gastrointestinal, respiratory, or central nervous system (CNS) abnormalities, or rash is present in fewer than 40% of patients (Table 53-1). Laboratory features often include leukopenia, thrombocytopenia, and mild-to-moderate elevations in serum hepatic transaminase activities (Table 53-2). Severe manifestations include meningoencephalitis, a toxic shock-like syndrome, respiratory insufficiency, acute renal failure, severe hepatitis, myocarditis, and prolonged fever of undetermined origin.<sup>26,60–66</sup> The case-fatality rate is 3%, and immunosuppressed persons (e.g., human immunodeficiency virus-infected, organ transplant recipients, or corticosteroid-treated) are at risk of overwhelming infection that is often fatal.<sup>12,66–68</sup> Early diagnosis and treatment are important to

prevent severe disease.<sup>1,5</sup> Pathologic features include perivascular lymphohistiocytic infiltrates without vasculitis, small noncaseating granulomas in hyperplastic bone marrow, and evidence of macrophage activation. Bone marrow is generally hypercellular or normocellular, indicating that pancytopenia, leukopenia, and thrombocytopenia occur as a result of peripheral sequestration or consumption of blood cells. Hepatocellular apoptosis and, in severe cases, necrosis of liver, spleen, and lymph nodes has been observed.<sup>26,64,68–70</sup> Except in immunocompromised patients, the presence of *E. chaffeensis* in lesions is scanty, suggesting that disease may be partly mediated by host factors.<sup>70</sup>

## PATHOGENESIS AND IMMUNITY

The pathogenesis of infection caused by *E. chaffeensis* is not well understood. Entry of *E. chaffeensis* into macrophages is mediated by binding of glycoprotein (gp) 120 and possibly other adhesins to host cell E- and L-selectin, probably at cholesterol-rich membrane lipid rafts or caveolae and glycosylphosphatidylinositol (GPI)-anchored proteins.<sup>39,71</sup> Binding of a heat-sensitive protein on *E. chaffeensis* initiates host cell phospholipase C and tyrosine kinase activation and mobilizes cytosolic free calcium in association with bacterial entry.<sup>39,73</sup> Entry is receptor-mediated and is impeded by transglutaminase inhibitors, but clathrin binding is not involved. Once internalized, *E. chaffeensis* alters the parasitophorous vacuole, leading to its accumulation of cellular transferrin receptors after activation of iron-responsive protein-1 that inhibits degradation of transferrin mRNA transcripts.<sup>17</sup> This effect leads to iron availability for bacterial growth and to redirection of the parasitophorous vacuole into a receptor salvage pathway that avoids lysosomal fusion. Genes involved in iron acquisition by *E. chaffeensis* are not regulated by an operon system, a situation that is evolutionarily divergent from other gram-negative bacteria. However, ferric (Fe III) iron is bound by a functionally conserved protein of the ferric binding protein (Fbp) family found extracellularly on dense-cored ehrlichiae that shares structural homology and iron binding capacity with Fbps of other gram-negative bacteria.<sup>73</sup> Down-regulation of host RAB5A, SNAP23, and STX16 with *E. chaffeensis* infection may underlie the altered endosomal trafficking and inhibition of its fusion with lysosomes.<sup>74</sup> The precise mechanism by which *E. chaffeensis* alters host gene transcription is not clear. Treatment with deferoxamine diminishes ehrlichial growth probably because the iron is utilized as a cofactor in oxidative

phosphorylation, a critical metabolic pathway for some *Ehrlichia* spp. that apparently cannot utilize glucose or glucose 6-phosphate as energy sources.<sup>17,75</sup>

Infection of macrophages with *E. chaffeensis* results in production of the cytokines interleukin (IL)-1 $\beta$ , IL-8, and IL-10, but not TNF- $\alpha$ , IL-6, or granulocyte macrophage colony-stimulating factor (GM-CSF), a profile that suggests a relative lack of proinflammatory induction signals and the potential for immunosuppression.<sup>76</sup> Inflammatory chemokines IL-8, MCP-1, and MIP-1 $\alpha$  are produced in response to *E. chaffeensis* and glycoproteins gp120 and gp200 through interactions with pattern recognition receptors. The cytokine response appears to be stimulated by *E. chaffeensis* carbohydrates, since periodation diminishes cytokine secretion. However, typical lipopolysaccharide-CD14 interaction does not account for the cytokine responses, since IL-1 $\beta$  induction by *E. chaffeensis* is not inhibited by monoclonal antibodies to CD14. When bound to immunoglobulin, macrophage-Fc receptor binding stimulates a strong proinflammatory response that could underlie local tissue injury with mounting immunity. Moreover, *E. chaffeensis* inhibits the expression of mRNA of IL-12, IL-15, and IL-18, cytokines that are key to the development of effective Th1 cellular immunity, and *E. chaffeensis* contains neither lipopolysaccharides or peptidoglycan pathogen associated molecular patterns associated with Toll-like receptor activation. Notably, downregulation of TLR2 and TLR4 genes in *E. chaffeensis*-infected cells occurs as a result of inhibition of p38 MAPK leading to reduced transcription factor PU.1 activity.<sup>40</sup> Furthermore, ehrlichiae down-regulate the expression of major histocompatibility complex (MHC) class II on infected cells, a potential mechanism of evading innate and acquired immune responses.<sup>77</sup> Animal models of monocytopathic *Ehrlichia* indicate that the humoral immune response, particularly to an epitope on the first hypervariable region of P28-19, a strong response by interferon- $\gamma$  (IFN- $\gamma$ )-producing CD4 Th1 cells, synergistic activity of IFN- $\gamma$  and TNF- $\alpha$ , and CD8 cytotoxic T lymphocytes act together to control ehrlichial infections.<sup>27,78–83</sup>

The mechanisms by which *E. chaffeensis* damage infected host cells in vitro and in vivo is unknown. Clearly, in vitro infection causes cytolysis of infected macrophages, macrophage-like cell lines, endothelial cell lines, some fibroblast cell lines, and human embryonic lung cells.<sup>9,29,84–86</sup> Some of these cells contain many *E. chaffeensis* morulae, suggesting that simple mechanical lysis may be involved. The in vivo correlate is significant necrosis associated with abundant *E. chaffeensis* organisms that are found in spleen, liver, and other mononuclear phagocyte-rich tissues of immunocompromised patients who become infected.<sup>26,68</sup> In contrast, most immunocompetent patients do not develop tissue necrosis, and *E. chaffeensis* can be difficult or impossible to identify in pathologic lesions including perivascular lymphohistiocytic infiltrates, granulomas, apoptotic hepatocytes, and apoptotic  $\gamma\delta$  T lymphocytes in blood during early convalescence.<sup>26,70,87</sup> It is these latter pathologic findings in the absence of significant quantities of *E. chaffeensis* that suggest the contribution of host responses in the disease process.

## DIAGNOSIS

Diagnosis is most often based on serologic studies,<sup>1,5,48</sup> which should include both *E. chaffeensis* and *A. phagocytophilum*

**FIGURE 53-1** Peripheral blood mononuclear cell with intracytoplasmic aggregate (morulae) of *Ehrlichia chaffeensis* (arrow). (Wright stain; original magnification  $\times 1000$ .)

antigens, since there is clinical similarity and serologic cross-reactivity occurs in some cases.<sup>50,88</sup> Seroconversion, fourfold rise in antibody titer to greater than or equal to 128, or a single serum titer greater than or equal to 256 in a patient with a consistent illness provides evidence of infection.<sup>50</sup> The development of recombinant antigens from *E. chaffeensis* holds promise for highly specific and sensitive serologic assays that may be useful in field conditions.<sup>57,89</sup> Peripheral blood smears should be examined for ehrlichial morulae (Fig. 53-1) in leukocytes, but except in immunocompromised patients, these are helpful in less than 10% of cases.<sup>1,5,90</sup> Polymerase chain reaction (PCR) amplification of *E. chaffeensis* DNA from acute-phase blood is between 56% and 95% sensitive, is highly specific, and provides timely information.<sup>50,90,91</sup> *E. chaffeensis* may be cultured from clinical samples in various cell lines, but the method is neither sensitive nor timely.<sup>9,36,50,90</sup>

## AGENT: *EHRlichia ewingii*

Known as a canine pathogen of neutrophils since the 1960s, *E. ewingii* was recently recognized as another cause of undifferentiated febrile illness following tick bites in geographic regions that overlap the distribution of HME and RMSF.<sup>4,12</sup> To avoid confusion with older nomenclature, it is prudent to avoid the term *human granulocytic ehrlichiosis* to refer to infection by *E. ewingii*. Despite its neutrophil host, the bacterium is more closely related to and shares more antigens with *E. chaffeensis* than with *A. phagocytophilum*.<sup>2,12,57</sup> It is presumed that a proportion of patients with a serologic diagnosis of HME actually have *E. ewingii*. This is in part based upon the known serologic cross-reactions and because 10%

of a cohort of suspected HME patients in Missouri were discovered to have *E. ewingii* instead.<sup>4</sup> *E. ewingii* is transmitted by *A. americanum* tick bites, although *Dermacentor variabilis* ticks may be naturally infected as well.<sup>92,93</sup> Similar to *E. chaffeensis*, white-tailed deer are persistently infected with *E. ewingii* in nature and are likely to be the most important reservoir, although a role for dogs as reservoirs has also been suggested.<sup>94,95</sup> Although only a small number of infected individuals has been described, the infection is most often recognized in immunocompromised persons, including those with HIV or with organ transplants.<sup>4,12</sup> In general, the infection is similar to HME, but it is milder and associated with fewer complications and no deaths. As the bacterium has not yet been cultivated in vitro, no specific serologic test is available and serodiagnosis cannot be reliably achieved using surrogate *E. chaffeensis* testing. Although infected neutrophils may occasionally be observed in peripheral blood, definitive identification currently depends on identification of *E. ewingii* nucleic acids in clinical samples.<sup>4,96</sup>

## ■ Human Granulocytotropic Anaplasmosis (HGA)

### AGENT: ANAPLASMA PHAGOCYTOPHILUM

*A. phagocytophilum* contains a number of protein antigens, and the immunodominant major surface protein-2 (Msp2) 44-kD proteins are encoded by at least 22 paralogs that appear to be individually transcribed and expressed within a single bacterial cell.<sup>19,97,98</sup> With time, recombination by gene conversion or more complicated combinatorial mechanisms generates antigenic variants that may promote persistence in reservoir hosts by immune evasion. In hosts that develop significant clinical signs, including humans, persistent infection is not documented. Msp2 complexes in *A. phagocytophilum* are also involved in adhesion to fucosylated surface proteins of neutrophils, including platelet selectin glycoprotein ligand (PSGL)-1.<sup>99–101</sup> After binding, the bacteria are internalized within endosomes that do not acquire any markers of maturation but contain bacterial proteins, some presumably related to a type IV secretion mechanism encoded in the genome.<sup>39</sup> A 155-kD protein called AnkA of unknown function is secreted by the bacterium, enters into the host cell nucleus, and complexes with host cell chromatin.<sup>102</sup>

### EPIDEMIOLOGY

Human granulocytotropic anaplasmosis (HGA; formerly, human granulocytotropic ehrlichiosis, HGE) was first identified in febrile patients who reported tick bites.<sup>10,11,103</sup> *Ixodes persulcatus*-complex ticks, including *Ixodes scapularis*, *Ixodes pacificus*, *Ixodes ricinus*, and *Ixodes persulcatus*, are naturally infected and except for *I. persulcatus*, each is proved competent for transmission of *A. phagocytophilum*.<sup>22–24,104,105</sup> Small rodents appear to be a major reservoir, but cervids, ruminants, raccoons, and rabbits, among many other animals, are infected in nature and may be important reservoirs as well.<sup>105–109</sup> Ticks are important hosts, but the lack of transovarial transmission emphasizes the critical role of the mammal-tick-mammal transmission cycle that is facilitated by *Anaplasma* persistence

in mammalian reservoirs.<sup>22</sup> HGA is most frequently recognized in the upper Midwest and northeastern United States and occasionally in northern California, areas that have a high incidence of *Ixodes* tick-related diseases,<sup>11,88,110</sup> including coinfections with Lyme disease and babesiosis.<sup>111–114</sup> Passive case collection reveals incidences as high as 58 and 51 cases per 100,000 population in the upper Midwest and Connecticut, respectively.<sup>88,115,116</sup> A worldwide high seroprevalence rate indicates that HGA probably is widely distributed and significantly underdiagnosed.<sup>117–120</sup> Most cases occur in May through July, when nymphal-stage ticks are active, although infections may be recognized even during winter months.<sup>88</sup>

On a worldwide basis, a high percentage of *Ixodes* spp. ticks, particularly those in the *I. persulcatus* complex, harbor *A. phagocytophilum*. The highest proportions of infected ticks are *I. scapularis*, found in the northeastern and upper midwestern United States, where infection may be found in up to 50% (median ≈11%).<sup>104,121,122</sup> Up to 7% (median 2%) of *I. pacificus* in California, and up to 33% of *I. persulcatus* and *I. ricinus* in Asia and Europe (median 5% and 4%, respectively) are infected.<sup>123–125</sup> Infection has also been demonstrated in *Dermacentor* ticks (*D. variabilis* and *D. occidentalis* in California), in Korean *Haemaphysalis longicornis*, and in several *Ixodes* spp. that seldom bite humans (*I. dentatus*, *I. trianguliceps*).<sup>107,124,126,127</sup> The anaplasmae spread from the tick's gut to the salivary gland and are inoculated into the dermis during tick feeding.<sup>24</sup> Transovarial transmission of *A. phagocytophilum* has not been demonstrated.<sup>22,23</sup>

### DISEASE

HGA is usually an undifferentiated febrile illness accompanied by headache, myalgias, rigors, and malaise; gastrointestinal, respiratory, and CNS abnormalities occur in a minority of patients<sup>88,110,128</sup> (see Table 53-1). Rash is rare. The median age is between 43 and 60 years with up to a 2:1 male predominance. Leukopenia (50% to 59% of patients), thrombocytopenia (59% to 92%), and elevations in serum hepatic transaminases (69% to 91%) are often present<sup>88,110,128</sup> (see Table 53-2). The manifestations of severe illness may include prolonged fever, shock, confusion, seizures, pneumonitis, acute renal failure, rhabdomyolysis, acute abdomen, hemorrhage, opportunistic infections, and death.<sup>88,110,129–133</sup> Misdiagnosis and late therapy contribute to severe morbidity. CNS infection and cerebrospinal fluid pleocytosis are rare, but reported complications include VIIth cranial nerve palsy, brachial plexopathy, and demyelinating polyneuropathy.<sup>134–136</sup> The case fatality rate is probably less than 0.5%, but 50% or more of infected patients require hospitalization, even in Europe, where disease is considered to be milder.<sup>88,103</sup> Opportunistic infections, including disseminated candidiasis, herpetic esophagitis, cryptococcal pneumonitis, and invasive pulmonary aspergillosis, are major causes of death and occur in patients with and without prior immunocompromise.<sup>88,129,137</sup>

### PATHOGENESIS AND IMMUNITY

The pathogenesis of HGA is not well understood but appears to be related to inadequate control of inflammation triggered by *A. phagocytophilum* infection.<sup>25,137</sup> Limited pathologic examinations of human tissue samples show changes

associated with macrophage activation, similar to those in *E. chaffeensis* infection, except lacking granulomas.<sup>88,129,137</sup> Neutrophil infection by *A. phagocytophilum* yields activation of host chemokine expression, motility, and degranulation but deactivation of endothelial cell adhesion and transcytosis, respiratory burst, and apoptosis.<sup>138–142</sup> Such changes allow longer persistence of infected cells in blood that can be ingested by biting ticks. However, the persistent activation may contribute to increasing inflammation and bystander cell injury accompanied by reduced ability to control other infections. Infection mediates early responses by interaction with macrophage Toll-like receptor–2 but not Toll-like receptor–4.<sup>143</sup> These interactions also promote specific immunity that incites production of Th1 proinflammatory cytokines, which are responsible for most inflammatory tissue injury in animal models.<sup>25</sup>

## DIAGNOSIS

Retrospective diagnosis is mostly by serologic tests using indirect fluorescent antibody and one of several *A. phagocytophilum* strains.<sup>103,144,145</sup> Occasional serologic cross-reactions to *E. chaffeensis* occur, but the homologous titer is usually higher.<sup>103,146</sup> A fourfold increase, seroconversion, or a high single antibody titer (usually  $\geq 64$ ) in a patient with a consistent illness is confirmatory. Careful examination of Giemsa- or Wright-stained peripheral blood smears (Fig. 53-2) may be diagnostic during the acute phase in 18% to 80% of patients.<sup>103</sup> PCR diagnosis is rapid and relatively sensitive, whereas culture is not timely.<sup>30,147</sup>

**FIGURE 53-2** Peripheral blood neutrophil with intracytoplasmic aggregate (arrow) of ehrlichiae in a patient with human granulocytic ehrlichiosis. (Wright stain; original magnification  $\times 1000$ .)

## Neorickettsiosis

### AGENT: *NEORICKETTSIA SENNETSU*

Originally recognized as an illness mimicking infectious mononucleosis in Japan, *N. sennetsu* infections have subsequently been documented in Malaysia and might occur unrecognized in other areas of Asia where raw or undercooked fish are eaten.<sup>148,149</sup> Recent investigations have identified complex cycles of bacterial infection of trematodes, the cercariae of which may infect snails and aquatic insects.<sup>150</sup> These are in turn ingested by a variety of animals, including fish, mammals, and birds, that may be reservoirs.<sup>151</sup> The infection has never been reported to cause fatal disease. Diagnosis by serology or culture is available in very few laboratories.

### TREATMENT

Because severity of HME and HGA may result from therapeutic delays, patients should be treated empirically. Most patients defervesce within 24 to 48 hours after starting doxycycline or tetracycline treatment.<sup>1,58,103</sup> Chloramphenicol should not be used, since in vitro minimal inhibitory concentrations cannot be effectively achieved in vivo.<sup>152–154</sup> The preferred adult regimen is oral doxycycline 100 mg twice daily or tetracycline 250 to 500 mg every 6 hours. For children, doxycycline 4.4 mg/kg in two divided doses per day or tetracycline 25 to 50 mg/kg/day in four divided doses is recommended. Therapy is administered for at least 3 days after defervescence, and some physicians treat for 14 to 21 days. *N. sennetsu* ehrlichiosis also responds to treatment with tetracycline. Some evidence suggests efficacy of rifampin.<sup>152–156</sup> Resistance to fluoroquinolones in *Ehrlichia* is mediated by an amino acid change in GyrA, suggesting the potential for resistance in *A. phagocytophilum* as well.<sup>157</sup>

### PREVENTION AND CONTROL

Simple precautions aimed at reducing tick exposure, including avoiding tick-infested habitats, wearing appropriate barrier clothing, using tick repellents, and removing attached ticks carefully and early, will lower the risk of disease acquisition. Conflicting data exist regarding a “grace period” during which transfer of the infectious agents is delayed immediately after tick attachment for HME and HGA. Some studies suggest a significant reduction in transmission if ticks are removed within 36 hours,<sup>158,159</sup> whereas others show a high transmission rate within 24 hours,<sup>160</sup> suggesting that daily tick removal may not be sufficient to prevent *A. phagocytophilum* transmission.

### WOLBACHIA-RELATED COMPLICATIONS OF FILARIASIS

*Wolbachia* spp. are endocyttoplasmic bacteria that are diversely spread throughout the world of insects, arthropods, helminths, and crustaceans.<sup>161</sup> These bacteria have diverse effects on the population dynamics of their hosts, usually leading to feminization of gender ratios associated with bacterial survival only in females. Examples that distort gender ratio include cytoplasmic incompatibility between infected and uninfected parents, parthenogenesis, and feminization of

genetic males, among others. In addition, endosymbiont bacteria of helminths can influence the survival of larval instars.

The inflammatory complications of lymphatic filariasis and river blindness are part of the pathogenesis of these infections.<sup>162</sup> These inflammatory processes are associated more often with death of the nematodes, whether naturally or by therapeutic intervention. Much of the subsequent inflammation can be attributed to innate responses of the host toward endosymbiont bacterial components, in part through CD14, Toll-like receptor-4, or other innate immune receptors.<sup>162</sup> Clinical trials to assess the effect of doxycycline treatment in lymphatic filariasis have demonstrated depletion of *Wolbachia* bacteria from adult worms and microfilariae, inhibition of embryogenesis, declining microfilariae quantities, and reduced spermatozoa present in female genital tracts.<sup>163,164</sup> Further assessment is required to show whether bacterial endosymbiont elimination will provide additional benefit for patients with lymphatic filariasis or river blindness.

# Q Fever

THOMAS J. MARRIE

## INTRODUCTION

Q fever is a disease that results from infection with the microorganism *Coxiella burnetii*. It was described by Dr. E.H. Derrick in August 1935, at which time he investigated an outbreak of undiagnosed febrile illness among workers at the Canon Hill Abattoir in Brisbane, Australia.<sup>1</sup> Shortly thereafter the organism responsible for this outbreak was isolated and eventually was named *Coxiella burnetii* in honour of Dr. Herald Rae Cox and Sir Frank Macfarlane Burnet, two scientists who contributed so much to our knowledge of this disease.<sup>2</sup>

## AGENT

*C. burnetii* is the sole species of its genus, and on the basis of 16S ribosomal RNA (rRNA) phylogeny it has been placed in the  $\gamma$  subdivision of Proteobacteria, with a specific but distant relationship to *Legionella*. It is an obligate phagolysosomal parasite of eukaryotes and measures  $0.3 \times 1.0 \mu\text{m}$  (Fig. 54-1).<sup>3</sup> It forms spores and has survived for 586 days in tick feces at

**FIGURE 54-1** Transmission electron micrograph of a cardiac vegetation from a patient with *Coxiella burnetii* endocarditis showing *C. burnetii* cells. (Magnification  $\times 23,335$ .)

room temperature, for longer than 160 days in water, for 30 to 40 days in dried cheese made from contaminated milk, and for up to 150 days in soil. In nature and in laboratory animals, it exists in the phase I state. Repeated passage of phase I organisms in embryonated chicken eggs leads to conversion to phase II avirulent forms.<sup>4</sup> This is accompanied by the loss of the methylated sugars virenose and dihydrohydroxystreptose, as well as a large number of other sugar components of the O-antigen side chain and some components of the outer core of the lipopolysaccharide.<sup>5</sup>

For some time, *Coxiella burnetii* has been viewed as a potential bioterrorism weapon. It is easy to disperse, extremely infectious with, for the most part, self-limiting infection, and does not damage the environment.

The 1,995,275 base pair genome and 37,393 base pair plasmid of *C. burnetii* phase I, Nine Mile strain, have been sequenced.<sup>6</sup> It possesses 2134 encoded proteins, 29 insertion sequence elements, 83 pseudogenes, and 13 proteins containing ankyrin repeat units. It contains homologues of *L. pneumophila*.

## EPIDEMIOLOGY

Q fever is found worldwide, including tropical countries, with the exception of New Zealand (no data are available about prevalence in Greenland and northernmost North America). In 1955, a review of the geographic distribution of Q fever indicated that it was found in Algeria, Belgian Congo (now Congo), the Cameroons (Cameroon), Egypt, Ubangi Shari (Central African Republic), Kenya, Libya, Madagascar, Rhodesia (now Zimbabwe), and South Africa.<sup>7</sup> More recent studies indicate that Q fever is endemic in Zimbabwe, Tunisia, and Northeast Africa.<sup>8-10</sup> Q fever is a zoonosis. There is an extensive wildlife and arthropod (mainly ticks) reservoir of *C. burnetii*.<sup>11</sup> Cattle, sheep, and goats are the animals that usually are the source of transmission of this microorganism to humans.<sup>11</sup> However, cats, dogs, and rabbits are also important in this regard. *C. burnetii* localizes to the uterus and mammary glands in female mammals. During pregnancy, reactivation occurs (although primary infection can occur as well), and the organism multiplies in the placenta, reaching  $10^9$  guinea pig infective doses per gram of tissue. These organisms are shed into the environment at the time of parturition. Man becomes infected after inhaling organisms aerosolized at the time of parturition or later when organisms in dust are stirred up on a windy day. Infected animals can shed *C. burnetii* in milk or feces for months. Outbreaks of abortion due to *C. burnetii* have been reported in goats and sheep but not in cattle. We have noted that the stillbirth rate among *C. burnetii*-infected cats is high—about 70%, compared with 10% for control cats.

## DISEASE

In most instances, humans become infected with *C. burnetii* following inhalation of contaminated aerosols.<sup>12</sup> In Nova Scotia entire families have developed Q fever pneumonia following exposure to infected parturient cats. Usually the cat gives birth in the house, and the person who cleans up the products of conception develops symptoms a day or two earlier than the remaining members of the family and is more severely ill. Certain occupational groups are at high risk of *C. burnetii* infection; these include abattoir workers

**Q fever (*Coxiella burnetii*)**

and veterinarians. Those who live in the vicinity of farms with infected animals are also at high risk of infection. High winds can disperse *C. burnetii*-contaminated dust 10 or more kilometers from these farms.<sup>13,14</sup>

It is likely that ingestion of *C. burnetii*-contaminated milk also causes infection, although the experimental evidence for this in humans is inconclusive. We have postulated that the route of infection determines whether or not one develops hepatitis or pneumonia following exposure to *C. burnetii*. It is our contention that ingestion of *C. burnetii* results in hepatitis, whereas inhalation of the organism results in pneumonia. In a mouse model that imperfectly mimicked these routes of

infection, we were able to show that intraperitoneal injection of *C. burnetii* resulted in hepatitis, whereas inhalation of *C. burnetii* resulted in pneumonia and no hepatitis. Experimental infection of humans by aerosol, however, has resulted in the development of hepatic granulomas.

Rarely, infection has occurred via the percutaneous route following crushing of infected ticks between the fingers or as a result of transfusion of contaminated blood. Vertical transmission from mother to infant can occur, and person-to-person transmission at the time of autopsy has rarely been reported. Recently, sexual transmission of Q fever has been documented, but this also seems to be very uncommon.

Several outbreaks of *C. burnetii* have occurred in institutions using pregnant sheep for research. These infected pregnant sheep were usually transported along crowded corridors, and a large number of employees in these institutions developed Q fever. It is now a universal recommendation that facilities that work with pregnant sheep must ensure that they are not infected with *C. burnetii* before they are brought into the facility.

The incubation period for Q fever in humans is about 2 weeks with a range of 2 to 29 days. A dose-response effect has been demonstrated both experimentally and clinically. *C. burnetii* is one of the most infectious agents known to man, as a single microorganism is capable of initiating infection. The resulting illness in humans can be divided into acute and chronic varieties.

**Acute Q Fever****Self-Limited Illness**

Self-limited illness is the most common manifestation of Q fever. In areas where Q fever is endemic, 12% or more of the population have antibodies to *C. burnetii*, and most of these infections are subclinical or undiagnosed. A study from the south of Spain found that 108 of 505 adults (21%) who had fever for more than 1 week and less than 3 weeks had Q fever. All of these patients had normal chest radiographs.

**Pneumonia**

This illness is more severe than the self-limited febrile illness. The major manifestations are fever; severe headache, often with retro-orbital pain; and cough. Surprisingly, a large number of patients with Q fever pneumonia may not have cough. In our studies in Nova Scotia of 51 patients with radiographically documented Q fever pneumonia, only 14 (27%) had cough.<sup>12</sup> This cough is usually nonproductive. In most instances the pneumonia is of mild to moderate severity and can be treated on an outpatient basis. However, occasionally the pneumonia can be severe and rapidly progressive, resulting in respiratory failure requiring assisted ventilation. Nausea, vomiting, and diarrhea occur in 10% to 30% of patients with Q fever pneumonia. The most common physical finding is inspiratory crackles. About 5% of Q fever patients with pneumonia have splenomegaly.

The radiographic features of Q fever pneumonia are variable. Subsegmental and segmental pleural-based opacities are common. Multiple rounded opacities are suggestive of this illness, especially the variety that follows exposure to parturient cats (Fig. 54-2). Pleural effusions occur in about one-third of patients. Hilar lymphadenopathy may also be present.

**FIGURE 54-2** Chest radiograph of a young man who developed Q fever pneumonia following exposure to the products of conception of an infected parturient cat. Note the multiple rounded pulmonary opacities.

Pulmonary tissue has been examined in only a small number of patients with Q fever pneumonia. In these instances the bronchial epithelial lining has been abnormal, and the interstitial space has contained edema along with infiltration by lymphocytes and macrophages. The alveolar spaces are filled with macrophages. We studied one patient with a pseudotumor due to *C. burnetii*. In this instance the lung mass was composed of a mixture of macrophages, multinucleate giant cells, plasma cells, and lymphocytes.

The white blood cell count is usually normal, although one-third of patients have leukocytosis. A slight elevation in hepatic transaminase levels occurs in almost all of these patients.

### Hepatitis

There are three presentations of Q fever hepatitis: (1) pyrexia of unknown origin with mild to moderate elevation of hepatic enzymes; (2) a hepatitis-like picture; (3) incidental hepatitis. Liver biopsy reveals distinctive “doughnut” granulomas, that is, a granuloma with a central lipid vacuole and fibrin deposits.

### Neurologic Manifestations

Aseptic meningitis or encephalitis complicates up to 1% of cases of Q fever. In some geographic areas the neurologic manifestations of Q fever are much more common than in others. In a study from Plymouth, England, Reilly and co-workers reported a 22% incidence of neurologic manifestations among 103 patients with Q fever.<sup>15</sup> These manifestations included residual weakness, recurrent meningitis, blurred vision, paresthesias, and sensory loss involving the left leg. Other neurologic manifestations of Q fever have included hallucinations,

dysphagia, and hemifacial pain suggestive of trigeminal neuralgia. The much higher rate of neurologic involvement in studies from the United Kingdom suggests that a neurotropic strain of *C. burnetii* may be circulating in that country. Rarely, behavioral disturbances, cerebellar signs and symptoms, cranial nerve palsies, extrapyramidal disease, Miller-Fisher syndrome, and demyelinating polyradiculoneuritis have been reported in Q fever.

### Chronic Q Fever

The usual manifestation of chronic Q fever is culture-negative endocarditis. Most of these patients have fever, and nearly all have abnormal native heart valves or prosthetic heart valves. Hepatomegaly or splenomegaly, or both, occur in about half of patients with Q fever endocarditis, and one-third have marked clubbing of the digits. Marked hyperglobulinemia ( $\geq 70$  g/L) is common and is a useful clue to diagnosis.<sup>16</sup> Microscopic hematuria is usually present. Arterial emboli complicate the clinical course of about one-third of patients with Q fever endocarditis.

In Q fever endocarditis, the vegetation is quite smooth and may form nodules on the valve. Microscopically, there is subacute and chronic inflammatory cell infiltrate, and many large foamy macrophages full of characteristic microorganisms are readily seen by electron microscopy (see Fig. 54-1).

### Q Fever in the Immunocompromised Host and During Pregnancy

Two recently recognized manifestations of Q fever include fever in immunocompromised patients and Q fever during pregnancy. The latter has been infrequently recognized but is a growing problem, especially in southern France and Israel. A recent study of 66 human immunodeficiency virus type 1 (HIV-1) seropositive persons living in Bangui, Central Africa Republic, found that 11 (16.7%) were also seropositive for *C. burnetii*. Two of the seven HIV-infected patients for whom clinical data were available had a history compatible with symptomatic Q fever.<sup>17</sup> Investigators in France found that 10.4% of 500 HIV-positive persons in Marseilles had Q fever antibodies at a titer equal to or greater than 1:225 compared with 4.1% of 925 healthy blood donors. They also found that 5 of 63 patients hospitalized with Q fever from 1987 to 1989 in Marseilles were HIV-positive. In France, 20% of patients with chronic Q fever were immunocompromised. These patients had cancer, chronic myeloid leukemia, acquired immunodeficiency syndrome (AIDS), renal transplantation, chronic alcoholism, or were receiving corticosteroid therapy or renal dialysis. Q fever has caused fatal interstitial pneumonia in an 11-year-old boy with the genetic condition, chronic granulomatous disease of childhood.

### PATHOGENESIS AND IMMUNITY

Over the past few years a considerable amount has been learned about the pathogenesis of *C. burnetii* infection. The attachment of virulent forms of *C. burnetii* to monocytes is mediated by  $\alpha v \beta 3$  integrin only<sup>18</sup> whereas the interaction of the avirulent form with monocytes requires  $\alpha v \beta 3$  and complement receptor 3 (CR3) integrins.<sup>18</sup> It is likely that the virulent variant inhibits the internalization mediated by CR3

through the impairment of cross talk between these two integrins.<sup>18</sup> *C. burnetii* avoids phagocytosis by interfering with the spatial distribution of complement receptor 3 on the surface of phagocytes.<sup>19</sup> Interferon  $\gamma$  mediates intracellular killing of *C. burnetii* by promoting apoptosis of infected monocytes through activation of caspase-3.<sup>20</sup> Interleukin-4 enables monocytes to support *C. burnetii* replication.<sup>21</sup> *C. burnetii* is not eradicated by the T-cell dependent immune response, and subsequent immunosuppression can lead to relapse.<sup>22,23</sup> Indeed, *C. burnetii* DNA persists in monocytes and bone marrow years after acute Q fever.<sup>24</sup> *C. burnetii* survives in monocytes from patients with chronic infection but not in monocytes from patients with acute Q fever or from seronegative control subjects.<sup>25</sup> This defect, which disappears when the patients are cured, is related to dysregulation of the cytokine network.<sup>26</sup> The secretion of soluble TNF receptor (TNF R75) is increased in these patients and may be responsible for the microbicidal defect,<sup>27</sup> which is also associated with IL-10 overproduction.<sup>28</sup> Furthermore, anti-IL-10 antibodies restore the microbial activity of the monocytes in vitro.<sup>28</sup> The complexity of the host-microorganism interaction is illustrated by investigators who used DNA microarray analysis and found that a total of 335 genes in the *C. burnetii*-infected human monocytic leukemia cell line THP-1 were up-or-down-regulated at least twofold.<sup>29</sup>

## TREATMENT AND PROGNOSIS

The prognosis is excellent in acute Q fever, with mortality being extremely rare. Fluoroquinolones and rifampin are the most active agents against *C. burnetii* in vitro. A 10-day course of tetracycline, doxycycline, or a fluoroquinolone will adequately treat acute Q fever. Macrolides have also been used to treat acute Q fever; however, some strains of *C. burnetii* are resistant to macrolides. Chronic Q fever should be treated with two antimicrobial agents for at least 3 years.<sup>30</sup> Some authorities recommend lifelong therapy for chronic Q fever. We currently use rifampin (300 mg twice daily) and ciprofloxacin (750 mg twice daily) as the agents of first choice in the treatment of chronic Q fever. Another regimen is doxycycline and hydroxychloroquine. The hydroxychloroquine alkalinizes the phagolysosome rendering doxycycline bactericidal.<sup>31</sup> In treating this condition, antibody titers should be measured every 3 months for the first 2 years. A progressive decline in antibody titer reflects successful therapy of chronic Q fever.

## PREVENTION AND CONTROL

A formalin-inactivated *C. burnetii* whole-cell vaccine protects against infection and has a 1% rate of induration developing at the inoculation site. The use of only seronegative pregnant sheep in research facilities and control of ectoparasites on livestock are measures that can reduce Q fever infection.

## Measles

CIRO A. DE QUADROS  
BRADLEY S. HERSH  
JON KIM ANDRUS

### INTRODUCTION

Measles is the most infectious virus known to humans.<sup>1</sup> Despite the availability of an effective preventive measure (live measles vaccine), measles continues to cause more deaths than any other single infectious agent.<sup>2</sup> The World Health Organization (WHO) estimates that in 1997 there were more than 36 million measles cases worldwide and nearly 1 million measles-related deaths, more deaths than those caused by the other vaccine-preventable diseases combined.<sup>3</sup> Most measles deaths occur among children living in developing countries. Globally, the disease accounts for more than 10% of deaths among children younger than 5 years of age, and it is especially lethal in infants younger than 1 year of age. Children may die from acute measles infection or from its sequelae, including encephalitis, pneumonia, diarrhea, and malnutrition. The disease thrives in cities, especially in deprived urban areas where crowding, poor sanitation, and low measles vaccination coverage ensure the ongoing circulation of the virus.

### AGENT

Measles is caused by an RNA virus of the genus *Morbillivirus* of the *Paramyxoviridae* family.<sup>4</sup> The virus is antigenically stable and is quite sensitive to ultraviolet light, heat, and drying.

### EPIDEMIOLOGY

Measles occurs in most areas of the world. In temperate climates, it occurs more often in late winter and early spring. In tropical climates, transmission appears to increase after the rainy season. In the absence of measles vaccination, epidemics often occur every 2 or 3 years and usually last between 2 and 3 months, although the duration varies according to population size, crowding, and population immunity. Where measles is common, most children will have been infected by the time they are 10 years old. Countries with relatively high vaccination coverage levels usually have 5- to 7-year periods with low measles incidence. However, as pools of susceptible hosts

build up and become large enough to sustain widespread transmission, explosive outbreaks may occur.

The incubation period of measles is approximately 10 days (range, 8 to 13 days) from the time of exposure until the onset of fever and approximately 14 days until the rash appears. Measles is most communicable 1 to 3 days before the onset of fever and cough, and transmission efficiency is high. Secondary attack rates among susceptible household contacts are reported to be more than 80%.<sup>5</sup> Outbreaks have been reported in populations in which only 3% to 7% of the individuals were susceptible.<sup>6-8</sup> There is a marked reduction in communicability of the virus following the appearance of the rash.

### DISEASE

The disease begins with a prodrome of fever, malaise, cough, and a runny nose. Conjunctivitis and bronchitis are commonly present. A harsh, nonproductive cough is present throughout the febrile period, persists for 1 or 2 weeks in uncomplicated cases, and is often the last symptom to disappear. Generalized lymphadenopathy commonly occurs in young children. Older children may complain of photophobia and arthralgias.

Within 2 to 4 days after the prodrome, symptoms begin; a characteristic red maculopapular (often referred to as "blotchy") rash usually appears behind the ears and on the face. In dark-skinned children the rash may not be as evident. The rash peaks in 2 or 3 days and is most concentrated on the trunk and upper extremities. The rash lasts from 3 to 7 days and may be followed by a brawny or fine desquamation (Fig. 55-1). Some children develop severe exfoliation, especially if they are severely malnourished.

Frequent complications from measles in developing countries include pneumonia, diarrhea, and otitis media.<sup>9</sup> Lower respiratory tract infections are the most important cause of significant morbidity and mortality in children with measles.<sup>10</sup> Pneumonia may be due to the measles virus alone or, more commonly, due to secondary infection with other viral agents or bacteria. Many infants and children may develop chronic diarrhea after acute measles illness.<sup>11</sup> Diarrhea is one of the major factors contributing to the adverse impact of measles on the nutritional status of children.<sup>12</sup>

Measles is more severe in malnourished children.<sup>13</sup> Additionally, measles may exacerbate malnutrition because of decreased food intake due to malaise, increased metabolic requirements in the presence of fever, or because parents and health practitioners inappropriately withhold food during an acute illness. Undernutrition may in turn lead to vitamin A deficiency and keratitis, resulting in a high incidence of childhood blindness in measles outbreaks.<sup>14</sup>

The most common neurologic manifestation of measles infection is febrile convulsions. Encephalitis or postinfectious encephalopathy occurs in approximately 1 in 1000 infected children. Subacute sclerosing panencephalitis is a rare chronic, degenerative neurologic disorder associated with the persistent infection of the central nervous system with a defective measles virus.<sup>15</sup> It may develop several years after a measles infection.

**FIGURE 55-1** Schematic clinical course of a typical case of measles. (From Krugman S, Katz SL, Gershon A, et al [eds]: *Infectious Diseases in Children*, 9th ed. St. Louis, Mosby-Year Book, 1992, p 224.)

## PATHOGENESIS

Measles virus is transmitted from person to person via respiratory droplets or airborne spray to mucous membranes in the upper respiratory tract or the conjunctiva. Common-source outbreaks associated with airborne transmission have been documented. Humans are the only reservoir for the virus. Although monkeys in captivity may become infected, measles transmission among them in the wild does not appear to be an important means for the virus to persist in nature.

Following exposure of a susceptible host, measles virus replicates in the respiratory tract, spreads and becomes amplified in local lymphatic tissues, and results in generalized infection via primary viremia.<sup>16</sup> Many tissues and organs of the body can be infected, including lymphoid tissue, skin, gastrointestinal tract, lungs, and liver. Measles infection has been shown to cause a suppression of the immune system which can persist several months after acute infection.<sup>17</sup> This immunosuppression is thought to account for the increased susceptibility of measles patients to secondary bacterial and viral infections that result in pneumonia and gastroenteritis.

## DIAGNOSIS

In countries where measles transmission is endemic and the disease is frequent, measles can be diagnosed with reasonable accuracy on clinical grounds alone. Koplik's spots may be seen on the buccal mucosa in more than 80% of the cases if careful daily examinations are performed soon before the rash appears.<sup>18</sup> Their presence is said to be pathognomonic of measles infection.

However, in areas where measles is no longer endemic due to high vaccination coverage, the large number of rashlike

illnesses occurring in childhood makes laboratory confirmation the key to definitive diagnosis. Many illnesses are accompanied by a rash and a variety of nonspecific symptoms. When examining for measles, it is important to consider rubella, scarlet fever, roseola, dengue fever, and the early stages of chickenpox in the differential diagnosis. Other diseases and conditions that may present in a similar form include Kawasaki syndrome, toxic shock syndrome, enterovirus and adenovirus infections, rickettsial diseases, and drug hypersensitivity rashes.

Measles virus isolation remains the "gold standard" for the laboratory confirmation of a suspected measles case.<sup>4,19</sup> However, due to the technical difficulties in isolating measles virus, this procedure is only performed in specialized laboratories. More commonly, measles infection is confirmed in the laboratory by documenting a serologic response to the measles virus in the host.

Measles-specific antibodies can be detected at onset of the rash and generally reach their peak approximately 1 month following infection. Immunoglobulin M (IgM) antibodies usually fall below the limits of detection by 6 weeks following infection, whereas IgG antibodies persist for many years after infection. Classically, the documentation of increasing titers of measles-specific antibody from acute to convalescent paired sera using complement fixation, the neutralization test, and hemagglutination inhibition assays was used to confirm acute measles infection.<sup>20</sup> In recent years, various enzyme immunoassays (EIAs) have been used to detect both measles-specific IgG and IgM antibodies.<sup>21-23</sup>

Testing serum for the presence of IgM antibodies via EIA to confirm clinical measles diagnosis is increasingly being used by many laboratories. A major advantage of using the IgM assays over previous approaches is that usually only

a single serum specimen is needed for measles confirmation. The measles IgM capture assay developed by the Centers for Disease Control and Prevention (CDC) has been found to be highly sensitive and specific for confirming measles infection when compared with traditional methods such as neutralization and hemagglutination inhibition.<sup>24,25</sup> Several commercial indirect measles IgM assays are available. The major advantage of these tests is that they are easy to perform and produce results in 2 or 3 hours versus 6 or 7 hours for the capture assay.<sup>22,26</sup> However, there are major differences between individual commercial assays. Some compare well with the IgM capture assay, whereas other tests have produced a significant number of false-positive and false-negative results.<sup>27</sup>

## TREATMENT AND PROGNOSIS

Other than supportive care, including fluids (such as oral rehydration solution), antipyretics, and nutritional therapy, there is no specific treatment for uncomplicated measles infection. However, antibiotics may be indicated for treatment of secondary bacterial infections, such as pneumonia. Moreover, the administration of vitamin A to hospitalized children with acute measles infections has been demonstrated to significantly reduce the risk of dying from measles. WHO recommends that vitamin A be given to all children with acute measles infection in areas that have experienced high measles mortality rates.<sup>28</sup> Many children require 4 to 8 weeks to recover their premeasles nutritional status.

In developed countries the case-fatality rate for measles tends to be low (between 0.1 and 1.0 per 1000 cases).<sup>29</sup> In developing countries, however, the overall case-fatality rate has been estimated at between 3% and 6% with the highest case-fatality rate occurring in infants 6 to 11 months of age.<sup>30</sup> In certain high-risk populations, case-fatality rates as high as 20% or 30% have been reported in infants under 1 year of age.<sup>31</sup> Moreover, extremely high measles mortality rates have been reported among infants and children living in refugee camps.<sup>32</sup>

## PREVENTION AND CONTROL

The original measles vaccines approved for use in children in 1963 were attenuated, live, and inactivated vaccines and are no longer used. The vaccines currently in use in most countries are further attenuated live measles virus vaccines. These are generally derived from the original Edmonston measles vaccine virus strain. The Moraten strain vaccine is used principally in the United States, whereas the Schwarz vaccine has been the strain most commonly used in other countries.<sup>33–35</sup> By 1982, virtually all countries in the world had incorporated measles vaccine into their routine vaccination schedules, and since then coverage has increased substantially. By 1990, the estimated overall global coverage for children by 2 years of age was approximately 80%.

Immunization with live measles vaccine has been demonstrated to be protective for more than 20 years, and immunity is thought to be lifelong.<sup>36</sup> Vaccine effectiveness is estimated to be between 90% and 95%.<sup>37</sup> The vaccine, however, does not provide protection in the presence of passively acquired maternal antibodies, which tend to wane between 6 and 9 months of age. Vaccine effectiveness increases steadily after

this age, reaching its maximum between the ages of 9 and 12 months. The development and persistence of serum antibodies following measles vaccination are lower but parallel to the response following natural measles infection. Peak antibody responses occur 6 to 8 weeks after infection or vaccination.

There are very few absolute contraindications to receiving measles vaccine. Measles vaccine should not be given to people with the following conditions or characteristics: severe immunosuppression, pregnancy, history of anaphylactic reaction to neomycin, or history of recent receipt of immunoglobulin or other blood products.<sup>38</sup> Vaccine can be administered safely and effectively to children with mild acute illnesses. Malnutrition should be considered an indication to vaccinate, not a contraindication. If a malnourished child becomes infected, the disease may aggravate his or her nutritional status and increase the chances of complications or death. Similarly, asymptomatic infection with the human immunodeficiency virus should not be considered a contraindication to measles vaccination.<sup>39</sup>

At the standard-dose, further attenuated measles vaccine is considered to be one of the safest vaccines available.<sup>40</sup> Approximately 5% to 15% of infants vaccinated with measles vaccine may develop a mild fever, and approximately 5% develop a generalized rash that lasts for 1 to 3 days. These symptoms may arise 5 to 10 days after vaccination and are generally mild and well tolerated.<sup>41</sup> Febrile convulsions have been reported to occur in approximately 1 in 1000 children following measles vaccination.<sup>42</sup> Severe neurologic events following measles vaccination, such as encephalitis and encephalopathy, are estimated to occur in less than 1 in 1 million vaccinees.<sup>43</sup>

Before the widespread use of measles vaccine, measles was a universal disease. Large epidemics tended to occur every 2 or 3 years. With the widespread use of measles vaccine, the interval between epidemics has increased, and the magnitude of outbreaks has decreased.<sup>44,45</sup> The vaccination strategy currently used to control measles in most developing countries has been to immunize infants through the routine health services delivery system, administering a single dose of measles vaccine between 9 and 12 months of age.

Most countries that have achieved and maintained high vaccine coverage with measles vaccine have reported a 90% or more reduction in the incidence of measles and measles-related deaths compared to the prevaccine era.<sup>46–49</sup> In a review of cost-effective health measures, the World Bank evaluated measles immunization as being one of the most cost-effective public health interventions currently available.<sup>50</sup>

Although measles vaccine coverage has markedly increased, measles outbreaks have continued to occur. Typically, several years of low measles incidence have been followed by gradually increasing measles activity, which culminates in the occurrence of a large measles outbreak. Even in areas where high coverage rates have been achieved and maintained, outbreaks have been reported.<sup>51</sup>

In the United States and other developed countries that have maintained relatively high levels of immunization coverage for several years, two distinct patterns of measles transmission have been observed. Outbreaks have been reported among populations of highly vaccinated school-age children as well as among unvaccinated preschool-age children living in densely populated, poor, urban areas.<sup>52</sup> The outbreaks among vaccinated school-age children have tended to be small and

self-limited, whereas those among unvaccinated preschool-age children have frequently been quite large and difficult to control.<sup>53</sup>

Large measles outbreaks have been reported in developing countries that have failed to achieve and maintain high levels of vaccination coverage.<sup>54,55</sup> Moreover, outbreaks have been reported from countries that have developed strong systems for vaccine delivery and have achieved high measles vaccination coverage.<sup>56–59</sup> Factors that have been implicated in these outbreaks include the failure to achieve and maintain sufficiently high levels of vaccination coverage, the occurrence of primary vaccination failure (the failure to seroconvert following vaccination) in 5% to 10% of vaccinated children, and the accumulation of susceptible children over time.

Efforts to control measles transmission, once an outbreak has started, have proved to be frustrating and often ineffective.<sup>60–62</sup> Due to the very high communicability of measles, many susceptible people have already been infected before the outbreak is recognized and control activities implemented. Given the difficulties in controlling measles outbreaks, increased efforts should be made to prevent them. This goal is accomplished by achieving and maintaining very high levels of measles immunity among infants and children.

There is a wide variation in estimates among mathematical modelers on what level of population immunity is necessary to stop or prevent circulation of measles virus.<sup>63</sup> This situation is understandable considering the large number of variables that affect measles transmission, including population density, living patterns, humidity, and the large number of assumptions that must be made in constructing an epidemiologic model. Nevertheless, it is clear that the efficiency of transmission is very high, and outbreaks have been reported in highly vaccinated populations.<sup>64,65</sup>

During the mid-1980s, measles virus continued to circulate and remained an important cause of morbidity and mortality, even in areas with relatively high measles vaccination coverage. This stimulated discussions of and research into improved mechanisms for measles control. In order to prevent the occurrence of measles outbreaks among highly vaccinated school-age children, some countries, including Chile, Denmark, Israel, Norway, Sweden, and the United States, instituted a routine two-dose measles vaccination schedule.<sup>66</sup> Moreover, increased efforts have been made to raise measles vaccination coverage among preschool-age children living in impoverished inner-city areas.<sup>67</sup>

To improve measles control in developing countries where, despite the presence of moderate to high vaccination coverage, measles virus was continuing to circulate and cause significant morbidity and mortality among infants and young children, work was conducted on developing and testing a higher potency measles vaccine that could provide measles immunity, in the presence of maternally acquired measles antibodies, to children younger than 9 months of age. Several studies found that a high-titer preparation of the Edmonston–Zagreb further attenuated live measles vaccine could stimulate high rates of seroconversion in 6-month-old infants.<sup>68–70</sup> Based on these results, the WHO recommended that high-titer Edmonston–Zagreb vaccine be used to vaccinate infants starting at 6 months of age in areas experiencing high-level measles mortality in infants and children.<sup>71</sup> Data from studies

in Senegal, however, suggested that girls vaccinated at 5 or 6 months of age with high-titer measles vaccine were, for an unexplained reason, at a higher risk of dying (late mortality from causes other than measles) than girls vaccinated at 9 or 10 months of age.<sup>72,73</sup> Based on these concerns, these vaccines are no longer recommended.<sup>74</sup>

An early success in interrupting measles transmission occurred in The Gambia, a country of approximately 1 million people located on the Atlantic coast near the western tip of Africa. Annual national measles immunization campaigns were begun in The Gambia starting in 1967.<sup>75</sup> The campaign strategy included village-by-village programs carried out by mobile vaccination teams. Initially, children 6 months to 6 years of age were immunized. Subsequent campaigns targeted young children not previously immunized. Measles transmission was interrupted within 1 year after the program began, and the country remained free of measles during the period 1968 to 1970.<sup>76</sup> Soon thereafter, the program was discontinued due to lack of financial support; measles virus was introduced from neighboring countries, and transmission was reestablished.<sup>77,78</sup> The Gambia, however, was the first developing country to interrupt measles transmission and to demonstrate that measles elimination was technically feasible.

In 1986, Cuba, based largely on the measles elimination experience of The Gambia as well as its own successful experience with polio eradication, developed a new national measles vaccination strategy using standard-titer, further attenuated measles vaccine. A mass measles vaccination campaign was conducted targeting all children 1 to 14 years of age, regardless of measles disease history or vaccination status. During a 6-month period, nearly 2.5 million children were vaccinated, resulting in a coverage of approximately 98%. Following the campaign, measles surveillance was strengthened, and the reported number of confirmed measles cases rapidly decreased to record low levels. Between 1989 and 1992, fewer than 20 confirmed measles cases were reported annually. Because of the accumulation of susceptible preschool-age children since the prior campaign, a repeat mass measles vaccination campaign was conducted in November 1993 targeting all children 2 to 6 years of age, regardless of prior vaccination or measles disease history. More than 880,000 children were vaccinated during this campaign, resulting in a 98% coverage. The last serologically confirmed case in Cuba occurred in June 1993.

After reviewing the measles elimination experiences of several countries, particularly The Gambia and Cuba, the Pan American Health Organization (PAHO) developed a regional measles elimination strategy that continues to evolve as additional experience accumulates<sup>79</sup> and which shares similarities to the highly successful PAHO polio eradication strategy that is currently being implemented throughout the world.<sup>80</sup> The strategy aims to rapidly interrupt measles transmission and to maintain the interruption in measles virus circulation by sustaining high population immunity. Measles case surveillance and measles virus surveillance are other key elements of the strategy.

The PAHO measles elimination strategy has three main vaccination components. First, a one-time-only “catch-up” measles vaccination is conducted. Attempts are made to vaccinate all children 9 months to 14 years of age, regardless

of measles disease history or vaccination status. The goal is to rapidly interrupt measles virus circulation through the achievement of high levels of measles immunity across a wide age cohort where most measles transmission is occurring.

Following the catch-up campaign, efforts are directed at strengthening infant immunization through routine vaccination services to slow down the accumulation of susceptible children and to help maintain the interruption of measles virus circulation. This component of the strategy is referred to as "keep-up" vaccination. Since the risk of an infant being exposed to circulating measles virus is low, the age of routine measles vaccination can be safely increased from 9 months to 12 months of age, thus providing an increase in measles vaccine effectiveness. Efforts are made to achieve 90% coverage in each successive birth cohort in every district.

Since measles vaccine is less than 100% effective and universal vaccination coverage is rarely achieved, by definition there will be an accumulation of susceptible infants and children over time, thus increasing the risk of a measles outbreak should the virus be reintroduced. To reduce the number of susceptible preschool-age children to low levels, periodic "follow-up" vaccination campaigns are conducted targeting all children 1 through 4 years of age, regardless of vaccination status or disease history. In addition to raising the level of measles immunity among previously immunized children, these campaigns provide measles vaccination to previously unvaccinated children and to those children who were vaccinated but who, for some reason, failed to respond to the vaccine. Through these periodic vaccination campaigns, which supplement vaccination coverage obtained through routine vaccination services, the strategy aims to achieve and maintain high measles population immunity in preschool-age and school-age children.

The interval between follow-up campaigns is determined by the vaccination coverage obtained through routine vaccination services. Campaigns are conducted when the estimated number of accumulated susceptible preschool-age

children approaches the number of infants in an average birth cohort. In practice, these campaigns will need to be conducted every 3 to 5 years.

By the end of 1995, all countries of Latin America and the English-speaking Caribbean had conducted catch-up measles vaccination campaigns (Fig. 55-2). The combined regional 1- to 14-year-old measles vaccination coverage is estimated to be 93%. The catch-up measles vaccination campaigns had an immediate impact in reducing measles incidence in the region (Fig. 55-3). The 2106 total confirmed measles cases reported during 1996 from Latin America and Caribbean countries is the lowest number ever reported up until that time and represents a 99% reduction compared with the cases reported in 1990, only 6 years earlier. Measles is now a rare infection in Latin America and the Caribbean. Surveillance evaluations conducted during 1995 and 1996 in Mexico, El Salvador, and Nicaragua did not detect any evidence of measles virus circulation.

Following the catch-up campaign in the English-speaking Caribbean in 1991, it has been more than 14 years since the last indigenous laboratory-confirmed case was reported from those countries. Similarly, it has been more than 16 years since the last laboratory-confirmed measles case was detected in Cuba. In other Latin American and Caribbean countries, measles transmission is occurring at extremely low levels, if at all. Most laboratory-confirmed cases have been sporadic and isolated in terms of time and place.

As a direct result of these successes, as well as the eradication of poliomyelitis from the Americas, in September 1994 the Ministers of Health of the Region of the Americas unanimously established the goal of measles eradication from the Western Hemisphere by 2000.<sup>81</sup>

The PAHO encourages countries to conduct follow-up campaigns every 4 years and to maintain high routine immunization coverage by targeting poor performing districts for additional support in order to protect against large outbreaks when importations occur. After essentially eliminating

**FIGURE 55-2** Annual reported measles cases in Latin American and Caribbean countries, 1974 through September 1996. (Data from the Pan-American Health Organization, Washington, DC.)

**FIGURE 55-3** Impact of a mass campaign on measles cases in the Americas, 1991–1995. In categories –10 to 0, data from 45 countries; +1, 44 countries; +2, 42 countries; +3, 26 countries; and +4, 23 countries. (Data from the Pan-American Health Organization Epidemiology Surveillance System, Washington, DC.)

endemic disease, in 2001–2002 a huge measles outbreak occurred in Colombia and Venezuela, resulting from an initial measles virus importation into Colombia. The virus genotype was D9 and transmission was stopped with supplemental immunization campaigns in November 2002. This most likely represents the last endemic transmission in the region. During this outbreak, Colombia reported 139 and Venezuela 2501 measles cases, respectively.

Beginning in 2003, Mexico also experienced an outbreak resulting from importation of measles virus. The virus genotype was H1 and was considered to be an importation because it had never been isolated previously in the Americas. H1 genotype is quite common in the Far East. Because population immunity was high, the outbreak remained relatively small and contained. During the outbreak period (April 2003 to July 2004) a total of 108 measles cases were reported. All but 2 cases occurred in the contiguous two states and Federal District of Mexico City.

These last outbreaks in the region highlight the fact that importations are to be expected if endemic transmission is still occurring in other parts of the world. The PAHO strategy has clearly demonstrated that regional measles eradication is indeed possible (Fig. 55-4), particularly when the strategies are implemented well.

The challenge for regions embarking on the PAHO strategy will be to maintain high population immunity with excellent immunization coverage and high-quality surveillance, especially to deal with importations. In addition, as Figure 55-4 demonstrates, implementation of measles elimination strategies should uncover the “hidden” disease burden of rubella and congenital rubella syndrome (CRS).

To that end, in September 2003, the Directing Council of PAHO adopted the initiative to eliminate rubella and CRS by the year 2010. Integrating the elimination of measles with the elimination of rubella will greatly enhance the capacity of countries to sustain progress. In addition, countries are encountering new opportunities to expand the benefits of disease control and elimination activities to other aspects of public health, most importantly in improving health care for women and reducing inequities in health care in the poorest countries.<sup>82,83</sup> It is expected that the adoption of similar strategies in countries worldwide will achieve global eradication of measles in the first decade of the twenty-first century.<sup>84,85</sup>

# Nipah and Hendra Viral Infections

RAMON FLICK  
PRAMILA WALPITA  
MARKUS CZUB

## INTRODUCTION

Over the past decade, outbreaks of severe diseases in humans, sea mammals, and Serengeti lions emerged and were in part attributed to infections with previously unknown paramyxoviruses. Of these, Hendra (HeV), Nipah (NiV), and Menangle viruses,<sup>1-3</sup> the previously unknown causative agents of diseases in humans and livestock in Australia and Malaysia, clearly merit the term emerging. Additionally, other novel paramyxoviruses have been isolated from bats,<sup>4</sup> tree shrews,<sup>5</sup> horses,<sup>6</sup> rodents, and humans<sup>7</sup>; however, infection with these viruses has not been associated with overt clinical disease. Only HeV and NiV are unusual among the paramyxoviruses in that they cause potentially fatal disease in a number of host species, including humans. Both viruses are designated as biosafety level (BSL)-4 agents.

In 1994, HeV caused an explosive outbreak of respiratory disease, claiming the lives of 14 horses and 2 humans in Australia.<sup>2,8</sup> In horses and cats,<sup>9</sup> natural and experimental infection with HeV is characterized by pulmonary lesions, including pulmonary edema and congestion, as well as hydrothorax and enlarged local lymph nodes.<sup>2,8,10,11</sup> Histologically, necrosis of alveolar walls and damage to small blood vessels in major organs are observed. In experimentally infected guinea pigs, there is generalized vascular disease; however, with only limited pulmonary pathology. The two human cases showed severe lung lesions and meningitis, respectively.<sup>12</sup>

NiV infections were first diagnosed in 1998–1999 in Malaysia.<sup>13-17</sup> Of 265 human cases of encephalitis, there were 105 fatalities.<sup>16,18-20</sup> The disease was initially attributed to Japanese encephalitis (JE), which is endemic in the region. However, epidemiologic considerations ruled out the possibility because JE virus is mosquito-borne and has no occupational association.<sup>21</sup> Moreover, JE virus vaccination drives were not effective in controlling the outbreak. Studies leading to isolation of the new agent were performed relatively rapidly. Infection with NiV leads to neurologic syndromes in humans and occasionally in pigs, although the latter show primarily mild respiratory disease.<sup>13,22</sup> The key histopathologic features in humans are systemic endothelial infection, vasculitis, thrombosis, ischemia, and necrosis. These changes are most pronounced in the central nervous system (CNS). In pigs, lesions are found in the brain or lungs. In the respiratory tract, lesions consist of tracheitis and

both suppurative and nonsuppurative bronchopneumonia and interstitial pneumonia. As a consequence of NiV infection in pigs, more than a million animals were culled.<sup>13,16,19,23,24</sup>

## AGENTS

### Classification

HeV and NiV belong to the family Paramyxoviridae of the order Mononegavirales. These viruses share similar genome organization and replication strategy. HeV and NiV have been proposed to form a new genus, *Henipavirus*, within the subfamily Paramyxovirinae.<sup>25,26</sup> Like other paramyxoviruses, henipaviruses have a single-stranded RNA genome with negative orientation. Unique features of henipaviruses within the subfamily Paramyxovirinae are their larger genomes (18.2 kb vs. 15.1 to 15.9 kb), longer untranslated regions, mostly at the 3' end, in each of the six transcription units, and a P protein that is more than 100 amino acids longer than any other known phosphoprotein in the family.<sup>26</sup> The nucleic acid sequence homology between HeV and NiV ranges from 70% to 85% for the coding regions and from 40% to 45% for the noncoding regions.<sup>27</sup> Homologies to other members of the paramyxovirus subfamily are less than 45%.<sup>13</sup>

### Biologic and Virologic Properties

The biologic properties of NiV and HeV are similar to those of other Paramyxovirinae in many respects, but quite distinct in several others. NiV and HeV grow to high titers in cell cultures derived from different organs of many species.<sup>2,8,27,28</sup> Both viruses induce a strong cytopathic effect in the form of syncytia.<sup>28-30</sup> The extent of diversity of the paramyxoviruses is further underscored by the fact that unlike the other paramyxoviruses, NiV and HeV are able to cause infection, disease, and death in a wide range of species including humans, pigs, horses, cats, and dogs. These findings raise questions about the evolutionary relationships with members of the order Mononegavirales. Electron microscopic studies of NiV and HeV show classical morphologic features of viruses belonging to the family Paramyxoviridae. They are pleomorphic enveloped viruses of variable diameter (120 to 500 nm), and in infected cells, they have helical filamentous nucleocapsids with the typical “herringbone” appearance. The HeV envelopes are covered with projections that give them a distinct “double fringed” appearance, while NiV envelopes are “single fringed.”<sup>11,31</sup> An additional unusual feature of NiV-infected cells, and to a lesser extent of HeV-infected cells, is the presence of tubule-like structures that are present at the cell periphery and in association with the endoplasmic reticulum and that appear to be involved in viral assembly and budding.<sup>11</sup>

### Replication

Recent evidence suggests that both NiV and HeV bind to the same glycoprotein receptor by a mechanism that is independent of sialic acid mediation.<sup>32</sup> Cleavage of HeV and NiV fusion protein precursor F<sub>0</sub> into disulfide-linked F<sub>1</sub> and F<sub>2</sub> subunits is a prerequisite for infectivity and is achieved by mechanisms unlike those of other paramyxoviruses.<sup>33,34</sup> Recent minigenome-based studies indicate that the sequence elements that control NiV and

HeV replication reside in the noncoding genomic and antigenomic promoter nucleotides.<sup>35</sup> Minigenome-based experiments and comparison with other paramyxoviruses suggest that during viral infection full-length genome copies are made via replication intermediate strands called the antigenome and that genomic and antigenomic RNAs serve as functional templates for transcription and replication only when they are encapsidated with the N protein. For the majority of paramyxoviruses including NiV, functional nucleocapsid formation requires that the total number of nucleotides in the genome length RNA be divisible by six (i.e., it obeys the *rule of six*).<sup>35–37</sup>

## EPIDEMIOLOGY

NiV and HeV are contagious, highly virulent, and capable of infecting several mammalian species. Subsequent to the outbreak in Malaysia and Singapore, there were smaller outbreaks of human NiV infection in Bangladesh in 2003–2004.<sup>38</sup>

Seroepidemiologic data indicate that fruit bats are a natural host for both NiV and HeV.<sup>9,39–43</sup> These animals roost in large groups in trees. It is possible that infected bats shed virus via saliva or urine and infect other animals and humans, although the exact mode of virus transmission is yet to be determined.<sup>44,45</sup> Data from the recent outbreak in Bangladesh suggest that human-to-human transmission of NiV is possible when close contact occurs.<sup>38,46</sup>

Under experimental conditions, NiV is able to infect cats, pigs, guinea pigs, and hamsters, while HeV infects horses, cats, and bats. Additional animal species may also be susceptible to infection. The natural disease in pigs is called porcine respiratory and encephalitis syndrome.<sup>22</sup> Although NiV did spread very rapidly among pigs under the farming conditions in Malaysia, a large percentage of the pigs remained asymptomatic, and the majority (85% to 95%) of the diseased pigs recovered.<sup>22</sup> Pigs transmit NiV to other pigs, other animals, and humans by an uncharacterized mechanism<sup>44,45</sup>; 93% of the afflicted humans in Malaysia had close occupational contact with infected pigs. Epidemiologic observations and laboratory findings indicate that porcine body fluids such as saliva, blood, and urine contain the virus. Subsequently, pig farmers and abattoir workers are at high risk for infection with NiV when exposed to NiV-infected pigs (or other animals).<sup>44</sup>

Under experimental conditions, HeV does not appear to be very contagious. Similarly, exposure of health-care workers to NiV-infected individuals during the Malaysian outbreak did not result in person-to-person transmission of infection.<sup>44,45</sup> On the basis of these and further epidemiologic data, it is speculated that transmission of HeV and NiVs occurs via aerosols or droplets and that humans are infected with low efficiency.<sup>47</sup> However, it is possible that natural infections are promoted by as yet unknown factors such as virus amplification in other hosts. Fruit bats, which have a high prevalence of antibodies to HeV, NiV, and other paramyxoviruses, might serve as an reservoir for further emerging paramyxoviruses.<sup>4,9,40–43</sup>

## DISEASES

### Nipah Virus Infection

Human NiV disease is a febrile encephalitis. Subclinical infection with NiV seems infrequent in humans; 75% of those

who seroconverted developed disease.<sup>19,20</sup> The incubation period based on the time of exposure until onset of fever ranged from a few days to 2 weeks with a mean incubation period of 10 days.<sup>18,19</sup> Initial symptoms were often described as influenza-like with sore throat, fever, headache, and myalgia. Clinical manifestations of encephalitic disease were dizziness, headache, vomiting, convulsions, reduced level of consciousness, and coma.<sup>16,18–20</sup> Late onset or relapse of NiV encephalitis occurred in 12 (7.5%) of those who survived the acute phase, and of these, 17% died. Respiratory tract involvement was present in 14% to 24% of patients in the Malaysian outbreak and manifested as nonproductive cough, fever, and myalgia. None had primary lung disease.<sup>20</sup> In contrast, pneumonitis was present in 3 of the 11 patients in the Singapore outbreak.<sup>16</sup>

### Hendra Virus Infection

The incubation period of HeV infection in humans is 4 to 18 days. Symptoms at onset are of severe influenza-like illness with high fever, headache, and myalgia. The first two human patients with HeV infection had respiratory symptoms; one died of respiratory failure and pneumonia, and the other recovered slowly 6 weeks after onset.<sup>17</sup> The second patient who died had neurologic disease that ran a protracted course; the initial illness was a mild meningoencephalitis. The patient continued to suffer from fatigue, developed epileptic seizures, and finally became comatose and died 13 months after exposure to HeV.<sup>10,12</sup>

## PATHOGENESIS

### Nipah Virus Infection

Postmortem studies of culture-confirmed NiV patients showed marked multiorgan vasculitis with endothelial damage in the arterioles, venules, and capillaries. In some cases, endothelial cells had lysed and sloughed into the lumen of the blood vessels; multinucleated giant cells, which are characteristic of paramyxoviral infections, were observed by light and electron microscopy.<sup>11,13</sup> The brain was the most severely affected organ.<sup>13,48</sup> In one study, evaluation at autopsy of microscopic features in the CNS showed necrotic lesions, perivascular cuffing, thrombosis, and vasculitis in 80% to 90% of the 30 cases examined; endothelial syncytia were present in 27% and meningitis in 57% of the patients.<sup>20</sup> The severity of the CNS pathology was demonstrated also by magnetic resonance imaging (MRI) analysis of 31 encephalitis patients in the Malaysian outbreak.<sup>49</sup> Other affected organs were the kidney, lung, and heart.<sup>13,20</sup>

Illness of pigs was largely due to respiratory disease and included a loud and distinctive cough and neurologic symptoms. The nature of the disease depended on the age of the pig. In sows and boars, symptoms of acute febrile respiratory illness predominated. Neurologic symptoms, when present, included spasms, seizures, head pressing, and pharyngeal muscle paralysis. Abortions occurred in diseased pregnant sows. In suckling pigs, mortality was higher, and the symptoms were a combination of respiratory and neurologic disease.<sup>13</sup> In pigs, respiratory tract involvement was the most common feature at postmortem examination. Giant cell pneumonia was present with multinucleated syncytial cells in the lung. NiV antigen was identified in the giant cells, the epithelial lining, the necrotic areas of the upper and lower respiratory tract, and renal tubular cells.<sup>50,51</sup>

## Hendra Virus Infection

The horse trainer who died of HeV infection had interstitial pneumonia. The second human who developed fatal disease died of encephalitis with histopathologic and MRI evidence of CNS lesions.<sup>10,12</sup>

In horses, the incubation period is between 8 and 11 days. An acute febrile respiratory or neurologic illness of short duration (1 to 3 days) results in death; symptoms include fever, rapid and shallow breathing, congested mucous membranes, ataxia, and head pressing.<sup>2,8,10</sup> The major pathologic changes in equines are in the lungs; the virus replicates in endothelial cells, apparently leading to endothelial damage, pulmonary edema, congestion, consolidation, and hemorrhage.<sup>10,11</sup>

## DIAGNOSIS

Clinical history of the patient is an important consideration in the choice of laboratory investigations and in the differential diagnosis. Since initial presentation of NiV disease is often non-specific, the geographic location, clinical history, and occupational exposure are important clues in the differential diagnosis. NiV should be an important consideration if the patient has been the endemic regions and JE is excluded.<sup>21</sup> MRI is useful in excluding JE because of the distinct difference in the appearance and distribution of brain lesions between NiV encephalitis and JE.<sup>21,49</sup> In the Malaysian and Singapore outbreaks, NiV disease showed abnormal cerebrospinal fluid (CSF) in 75% of the patients and abnormal liver function tests in 50%<sup>18,19,24</sup>; thrombocytopenia and leukopenia were also noted.<sup>16</sup> Serology provides an etiologic diagnosis<sup>52,53</sup>; NiV-specific immunoglobulin M (IgM) and IgG levels were detected by enzyme immunoassays in 100% of the patients by day 12 and day 25, respectively.

Virus isolation is of limited availability because NiV is a BSL-4 agent. However, when biocontainment facilities are available, virus can be isolated from urine, CSF, throat and nasal secretions<sup>47,54</sup> and tissues from various organs of the body.<sup>28</sup> A variety of cells are permissive for NiV cultivation although Vero (green monkey kidney) cells are used most frequently.<sup>26–28</sup> Virus isolates showing classical syncytial cytopathic effect<sup>1,28</sup> should be confirmed by immunostaining of virus-specific antigen. A real-time reverse transcription–polymerase chain reaction (RT-PCR) assay provides a sensitive and specific means to detect virus and to measure the virus load.<sup>55</sup> However, caution has to be taken with negative PCR results because the source of tissue and the time of sampling may determine a negative result despite an ongoing infection.

The biocontainment requirements also limit the use of virus isolation for HeV diagnosis. Nevertheless, a variety of cell lines are permissive for HeV propagation. Vero cells are generally used for cell culture,<sup>2,8,13,27</sup> and when infected show marked syncytial cytopathic effect that is distinct from that produced by NiV.<sup>1,28</sup> Immunostaining demonstrates viral antigen in formalin-fixed, paraffin-embedded tissues. Electron microscopic studies identify the classical morphology of the virus with its double-fringed envelope.<sup>11,31</sup> A variety of tests are available for serodiagnosis of HeV, including enzyme immunoassay (EIA), blocking EIA, neutralization assay, indirect immunofluorescence, and immunoblotting.<sup>52,53</sup> RT-PCR can detect HeV in formalin-fixed tissues.<sup>52,53,55</sup>

## TREATMENT AND PROGNOSIS

No specific treatment is available for NiV or HeV infection. Whether ribavirin might be of value in the treatment of NiV infection remains unclear and requires blinded, randomized, controlled trials.

Thus, treatment of infected humans is supportive and designed to sustain life and relieve symptoms. Prognosis is poor, since the case-fatality rate is high (around 40% with NiV in humans<sup>16,18–20</sup>). Survivors of encephalitis may suffer lifelong disabilities.

## PREVENTION AND CONTROL

In an outbreak, the source of infection needs to be identified and prevented from further transmitting the infection. Preventive measures include clinical care in an isolation ward and culling of infected animals. Experimental vaccines against NiV show promising results in animals; however, it is doubtful whether these vaccines will become available for humans.

# Human Herpesvirus Infections

S. DAVID HUDNALL  
LAWRENCE R. STANBERRY

## INTRODUCTION

There are currently nine herpesviruses known to afflict humans—in eight cases, the human is the only known host, while in one case the human rarely plays accidental host to a simian virus. All herpesviruses share certain genetic structural and biologic characteristics, yet exhibit a bewildering range of clinical disease manifestations (Table 57-1). All herpesviruses have relatively large and complex double-stranded DNA genomes ranging in size from 125 kbp to 229 kbp with large (greater than 100 bp) reiterated sequences called terminal repeats present at the end(s) of the linear genome. The herpesvirus genome encodes more than 60 genes, including many involved in nucleic acid metabolism and DNA synthesis. The herpes virion is a 120-nm to 800-nm particle composed of an estimated 30 to 35 proteins and consisting of an electron-dense toroidal core containing a linear double-stranded DNA molecule enclosed sequentially by a 100-nm icosadeltahedral nucleocapsid with 162 capsomers, an amorphous tegument layer, and a trilaminar lipid envelope. The envelope is largely derived from host cell nuclear membrane but contains viral glycoproteins important in target cell binding and as targets for neutralizing antibodies. These shared physical properties explain the remarkable ultrastructural similarity of all herpesviruses. After fusion with the target cell, the unenveloped virion migrates to the cell nucleus where the capsid is lost and the linear DNA molecule circularizes in the terminal repeat region(s) to form the closed circular (episomal) form characteristic of the latent cycle. The episomal form replicates during the latent cycle in synchrony with the host genome during S (synthesis) phase through the action of host cell DNA polymerase, while in the lytic cycle replication is driven by viral DNA polymerase. Replication proceeds by a rolling circle mechanism which yields end-to-end concatamers, which are then cleaved at the terminal repeats into monomers. Integration of viral DNA into the host genome does sometimes occur but apparently does not contribute significantly to virus persistence or viral-induced cell transformation.

All herpesviruses exhibit two distinct cycles of infection—the latent and lytic cycles. The latent cycle is characterized by gene expression limited to a few regulatory genes, the products of which are presumably required for maintenance of intranuclear episomal DNA. All viral gene expression is mediated

by host cell RNA polymerase II. The latently infected host cell provides a means for virus persistence by remaining viable and serving as a poor target for the host immune system, while retaining the capability of producing infectious virus after switching into the lytic cycle. The lytic cycle is characterized by activation of a large number of viral genes involved in viral DNA replication and virion assembly, most often leading to inhibition of host cell macromolecular synthesis, release of infectious virus, and host cell death. The latent and lytic cycles play complementary roles for the herpesvirus—latency allows for viral persistence while lysis allows for viral spread. However, the factors which govern the balance between the latent and lytic states are poorly understood. Further details of viral replication are available in several excellent texts.<sup>1-5</sup>

The herpesviruses are currently classified on the basis of biologic characteristics by the Herpesvirus Study Group of the International Committee on the Taxonomy of Viruses into three subfamilies—the alpha-, beta-, and gammaherpesviruses. The alphaherpesviruses—herpes simplex virus (HSV), varicella-zoster virus (VZV), cercopithecine virus 1 (CHV-1)—have high reproductive rates with rapid spread and lethal lysis of infected cells in vitro. Although mucocutaneous epithelia are initially infected, latency is established in the neurons of sensory ganglia. The betaherpesviruses—cytomegalovirus (CMV), human herpesviruses 6 and 7 (HHV-6, HHV-7)—have low reproductive rates with slow spread and nonlethal cytomegalia of infected cells in vitro. Infection may be widespread while latency is likely established in secretory epithelial tissues and leukocytes. The gammaherpesviruses—Epstein-Barr virus (EBV), human herpesvirus 8 (HHV-8)—infect lymphocytes, epithelial tissues, and mesenchymal cells, while latency is likely established in B lymphocytes. The gammaherpesviruses are distinct from the other herpesvirus subfamilies in being causally linked to malignant lymphoid, epithelial, and mesenchymal tumors in humans.

The human herpesviruses are distributed throughout the world with no significant geographic variation. In many developing areas, including the tropics, children appear to acquire most herpesvirus infections, with the exception of VZV, at an earlier age than in developed countries, presumably due to greater transmissibility and exposure from overcrowding and poor general hygiene. In most cases, primary infection is acquired in early childhood and, with the exception of VZV (varicella), is usually asymptomatic. Symptomatic primary infections with the alphaherpesviruses usually present as mucocutaneous vesicular eruptions—HSV-1 most often localized to the oral region, HSV-2 localized to the genital region, while VZV is most often generalized to cutaneous areas. Primary symptomatic CMV and EBV infections commonly present in young adults as mononucleosis syndromes with pharyngitis and adenopathy, while HHV-6 infection usually presents with fever and a characteristic macular rash. Little is known of the clinical characteristics of primary HHV-7 and HHV-8 infection. Human infection with CHV-1 usually leads to HSV-like vesicular lesions at the site of inoculation (animal bite) followed rapidly by neurologic symptoms. Those at greatest risk of serious herpesvirus infection include the very young (fetus, newborn) and the immunocompromised (malnourished, persons with acquired immunodeficiency syndrome [AIDS], organ transplant recipients, and

**Table 57-1 Clinical Characteristics of Human Herpesvirus Infection**

<b>Virus</b>	<b>Congenital/Neonatal Infection</b>	<b>Primary Infection</b>	<b>Recurrent Infection</b>	<b>Ocular Disease</b>	<b>Skin Disease</b>	<b>CNS Disease</b>
HSV-1	Rare	Gingivostomatitis, usually in childhood	Herpes labialis	Keratoconjunctivitis, keratitis; most common cause of ulcerative eye infection	Oral mucocutaneous vesicular eruption; intraoral ulcers	Most common sporadic acute viral encephalitis in adults
HSV-2	Congenital infection uncommon; systemic infection in neonate	Herpes genitalis, usually in young adults; a common ulcerative genital infection	Herpes genitalis; usually very mild	Rare	Genital mucocutaneous vesicular eruption	Rare; encephalitis in neonates
VZV	Rare congenital syndrome with skin/autonomic defects; neonatal infection with typical rash	Varicella (chickenpox), usually mild in childhood; adult onset in tropics more severe	Zoster (shingles), usually in older adults	Ophthalmic zoster; rare in varicella	Vesicular eruption; generalized in varicella; dermatomal distribution in zoster	Rarely in elderly with cranial nerve zoster (Ramsay-Hunt syndrome)
CMV	Growth and mental retardation (cytomegalic inclusion disease)	Often asymptomatic in childhood; mononucleosis usually in adults	Rare; pneumonia and colitis in immunodeficient	Retinitis in congenital infection	Rare ulcerative perineal eruption in immunodeficient	Encephalitis in congenital infection
EBV	Rare	Often symptomatic in childhood; mononucleosis usually in adolescents/young adults	Burkitt's lymphoma; AIDS lymphoma; posttransplant lymphoma; nasopharyngeal carcinoma	Not reported	Rare maculopapular eruption of trunk and arms	Rare
HHV-6	Rare	Exanthem subitum, in young children	Unknown	Not reported	Maculopapular eruption of trunk and neck	Rare
HHV-7	Rare	? HHV-6-negative exanthem subitum	Unknown	Not reported	? Maculopapular eruption of trunk and neck	Not reported
HHV-8	Not reported	Not reported	Kaposi's sarcoma; primary effusion-based B-cell lymphoma; ? lymphoma; ? Castleman's disease	Not reported	Multifocal macules, plaques, or nodules (Kaposi's sarcoma)	Not reported
CHV-1	Not reported	Vesicular dermatitis at bite site with paresthesia	Not reported	Not reported	Painful vesicular eruption at bite	Severe encephalitis

CHV-1, cercarial dermatitis; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV-6-8, human herpesviruses 6-8; HSV-1, herpes simplex virus type 1; HSV-2, herpes simplex virus type 2; VZV, varicella-zoster virus.

cancer patients), who have either immature or deficient immune systems. In these cases, dissemination to visceral organs and the central nervous system (CNS) often leads to a poor outcome.

In most cases, following primary infection herpesviruses persist in the host in a latent state with no recurrence of clinical symptoms. However, a significant number of healthy seropositive persons (20% for EBV) will continue to shed infectious virus intermittently and contribute to the ubiquitous distribution of the herpesviruses. Clinical recurrence in most cases is the result of reactivation of latent infection rather than reinfection. In some cases (e.g., HSV-2), recurrence leads to a clinical illness closely resembling that of the primary presentation but usually of lesser severity (herpes genitalis), whereas in other cases (e.g., VZV) recurrence leads to a clinical illness which does not resemble the primary presentation and is often of greater clinical severity (herpes zoster). Reactivation may be induced by a variety of stimuli, including sunlight, emotional stress, menses, poor nutritional status, severe illness, trauma, or immunosuppression—all perhaps leading to a transient period of immune suppression. The herpesviruses are susceptible to nucleoside analogues such as vidarabine, trifluridine, penciclovir, acyclovir, ganciclovir, famciclovir, and valacyclovir, as well as the viral DNA polymerase inhibitors foscarnet and cidofovir.<sup>6,7</sup> Antiviral drug resistance to both nucleoside analogues and DNA polymerase inhibitors is of increasing concern.<sup>8</sup> Prevention of VZV infection is now attainable by use of a Food and Drug Administration (FDA)–approved live attenuated varicella vaccine (Varivax). Subunit vaccines against CMV and EBV are under development.

## ■ Herpes Simplex Viruses

### AGENT

The infectious nature of HSV was first demonstrated by induction of typical dendritic corneal lesions in rabbits from material obtained from human herpes keratitis and herpes labialis lesions.<sup>9</sup> The distinction between the two virus strains, HSV-1 (above-the-belt lesions) and HSV-2 (below-the-belt lesions), was first made in 1968,<sup>10</sup> although it is now recognized that either virus strain can cause comparable primary infection at any anatomic site.<sup>11</sup> HSV virions contain 150 kbp of linear, double-stranded DNA encoding at least 84 proteins.<sup>12</sup> HSV gene expression may be temporally classified into three distinct phases termed alpha (immediate early), beta (early), and gamma (late). Alpha genes are expressed without prior protein synthesis and are largely involved in transcriptional transactivation. Beta genes are dependent upon prior alpha gene expression and encode proteins required for DNA replication. Gamma genes are dependent upon prior DNA replication and encode virion structural proteins. Beta and gamma gene expression is accompanied by inhibition of cellular DNA, RNA, and protein synthesis and by cell death.<sup>13</sup> At least 12 glycoproteins are embedded in the viral envelope; some of these glycoproteins are important in viral infectivity and also as targets of the immune system.<sup>14</sup> The antigenic difference between glycoprotein G (gG) from HSV-1 (gG-1) and HSV-2 (gG-2) is the basis for serologic distinction of the two

HSV types.<sup>15</sup> In culture, HSV inhibits host cell macromolecular synthesis and causes rapid cell lysis of a number of cell types.<sup>16,17</sup>

### EPIDEMIOLOGY

The two strains of the herpes simplex virus, HSV-1 and HSV-2, differ not only in genetic sequence (with approximately 50% sequence homology) but also in biologic and clinical behavior. Both strains are found worldwide with high seroprevalence and with no seasonal variation or epidemics. HSV-1 infection is primarily acquired during childhood and adolescence and is more widespread than HSV-2 infection, which is usually acquired during adolescence and early adulthood. HSV-1 seroprevalence exhibits marked geographic variation with relatively low rates (less than 70%) in France, Japan, the United States, and Sweden, and relatively high rates (greater than 95%) in Spain, Italy, Africa, China, and Latin America. Seroprevalence is higher in low socioeconomic groups and in developing regions—by adolescence, up to 80% have anti-HSV-1 antibodies in the developing world, while by the third decade only 60% are seropositive in the developed world.<sup>18</sup> HSV-2 seroprevalence is generally highest in Africa and South America, intermediate in northern Europe and North America, lower in western and southern Europe, and lowest in Asia.<sup>19</sup> Age-specific HSV-2 prevalence is higher in women than men and in populations with higher-risk sexual behaviors. HSV-1 infection is most often acquired through oral transmission following direct contact with either an acutely infected person or a healthy individual who is asymptotically shedding virus. Primary or initial HSV-1 infection is most often asymptomatic.<sup>20</sup> Asymptomatic oral viral shedding is common in children (20%) while less common (3%) in adults.<sup>21,22</sup> However, unlike varicella, there is no apparent increase in transmission in day-care environments.<sup>23</sup>

### DISEASE

Symptomatic primary infection follows an incubation period of 2 to 20 days and is characterized by fever, sore throat, cervical lymphadenopathy, and a vesicular rash in the oral cavity termed *gingivostomatitis*.<sup>24</sup> In adolescents and adults, symptomatic primary HSV-1 infection is most often characterized by a mononucleosis syndrome with pharyngitis, cervical lymphadenopathy, and fever.<sup>25</sup> Acute HSV-1 keratoconjunctivitis is a common cause of viral eye infection in adults in developed countries and presumably in the tropics and in most cases heals without corneal scarring. Recurrent herpes (HSV-1) keratitis manifests as a corneal ulcer with a characteristic dendritic branching pattern which may progress and lead to corneal scarring and loss of vision. Necrotizing herpetic retinopathies are rare, potentially blinding retinal disorders resulting from ocular infections with HSV-1 or HSV-2, varicella-zoster virus, or cytomegalovirus.<sup>26</sup> Herpetic dermatitis may be seen in athletes (herpes gladiatorum or scrumpox) from person-to-person abrasion, in health-care workers on their unprotected fingers (herpetic whitlow), and in patients with eczema in which herpetic superinfection leads to a severe disseminated form termed *Kaposi's varicelliform eruption*.<sup>27–29</sup> Although rare, HSV-1 encephalitis is the most common cause of acute sporadic viral

encephalitis beyond the neonatal period. The early onset of seizures and localizing signs indicating temporal or frontal lobe involvement are characteristic.<sup>30</sup> Disseminated HSV infections outside the neonatal period are rare but can occur in immunocompromised patients and occasionally in the pregnant woman. Infection in these patients may disseminate by direct extension from the upper oral cavity to involve the trachea and lungs and/or the esophagus and gastrointestinal tract, or dissemination may occur via viremia to involve visceral organs and the central nervous system.<sup>31,32</sup> HSV-1 is also a common cause of genital herpes.<sup>33–37</sup>

Latent HSV-1 in cervical and trigeminal sensory ganglia may reactivate to cause recurrent infections; it is estimated that 20% to 40% of primary infections are followed by at least one symptomatic recurrence. The most common recurrent HSV-1 infection is herpes labialis (fever blisters or cold sores).<sup>38,39</sup> It is characterized by a vesicular eruption on or about the lips (Plate 57-1A; Fig. 57-1). Recurrent HSV-1 infections may also be asymptomatic or take the form of keratoconjunctivitis, keratitis, retinitis, whitlow, cutaneous lesions (gladiatorium), encephalitis, erythema multiforme, duodenal ulcer, or genital herpes, although HSV-1 tends to cause fewer episodes of recurrent genital herpes than does HSV-2.<sup>35,36</sup> HSV-2 infection is most often acquired by sexual transmission in adolescents or young adults.<sup>40</sup> It is estimated that 80% to 90% of HSV-2 infections are asymptomatic, but asymptomatically infected individuals shed virus from genital sites and may transmit virus to sexual partners or newborn infants.<sup>41–44</sup> The most common presentation of HSV-2 infection in adults is herpes genitalis, which is also the most common cause of genital ulcers in the developed world. The classical presentation of genital herpes is a painful vesicular eruption of the female vulva (Plate 57-1B), vagina, cervix, urethra, and perineum, and of the male glans, prepuce, and shaft of the penis. The vesicular lesions typically progress to form shallow painful ulcers, which eventually crust and heal without scarring. Anorectal involvement and cutaneous lesions on the buttocks and thighs are relatively common and may result from anogenital sex or from zosteriform spread of virus from genital to rectal or other adjacent cutaneous sites. Primary infection is often complicated by aseptic meningitis and urinary

retention and rarely by transverse myelitis and autonomic dysfunction. Recurrent HSV-2 genital herpes is quite common, and more than 50% of persons with symptomatic primary infection experience recurrences, typically four to five outbreaks in the first year. Recurrent HSV-1 genital herpes is relatively uncommon, and the patients that experience recurrences following a primary infection typically experience only a single outbreak annually. Symptomatic recurrent genital herpes tends to be considerably less severe than the initial outbreak. Subclinical HSV-2 genital infections (asymptomatic shedding) are very common following initial infection in both patients who have experienced symptomatic initial infection and those that are asymptomatically infected. HSV shedding, as detected by culture, occurs on about 3% of days for immunocompetent men and women, and more frequently if measured by polymerase chain reaction (PCR) methods or if the individual is HIV-infected.<sup>42,45–47</sup>

HSV infection of the fetus or newborn is referred to as neonatal herpes. Most cases occur as a consequence of spread of virus from a mother with genital HSV infection to her infant at the time of delivery, although cases of intrauterine transmission and postpartum acquisition have been documented.<sup>44,48,49</sup> Intrauterine infection early in gestation is a rare cause of intrauterine death and spontaneous abortion.<sup>50</sup> Perinatally acquired neonatal herpes, as with maternal genital herpes, may be due to either HSV-1 or HSV-2. The risk of maternal-infant transmission is greatest (approaching 50%) for women experiencing primary genital infection near term, while the risk of transmission for women with a history of genital herpes prior to pregnancy is less than 2%. The difference in risk of transmission probably relates to the presence or absence of HSV-specific maternally derived antibodies that afford the infant some protection against infection and the amount of virus present in the genital tract (high concentrations during the initial infection and several logs less virus during recurrent infections).<sup>51</sup> Most cases of neonatal herpes result from unrecognized or asymptomatic maternal genital herpes.<sup>44</sup> Unlike other HSV infections, asymptomatic neonatal herpes probably does not occur. Infection is initiated at a portal of entry: the conjunctival sac of the eye, the nasopharynx, or at a site where the skin is abraded such as occurs with the use of a scalp electrode. Infection that remains localized to the portal of entry results in skin, eye, or mouth (SEM) disease. Without treatment, SEM disease typically progresses to more severe forms of the infection through direct extension to the lungs to produce a necrotizing pneumonitis, via intraneuronal spread to cause CNS disease or through viremic spread to visceral organs resulting in disseminated infection.<sup>51</sup> There is approximately an equal distribution of cases in the SEM, CNS, and disseminated disease categories, but outcome, while generally good for infants with SEM disease, is very poor for infants with disseminated infection with mortality approaching 50% despite antiviral therapy. Infants with CNS disease are likely to survive, but those with HSV-2 infection are very likely to suffer neurological sequelae.<sup>52</sup>

## **PATHOGENESIS AND IMMUNITY**

In vivo, primary infection begins with replication of virus in epithelial cells, which results in cell death. Virus gains entry to sensory nerve fibers that innervate the portal of entry and

move via a retrograde axoplasmic transport process to the neuron cell body located in sensory ganglia, cervical and trigeminal ganglia in the case of oral infection, and sacral ganglia in the case of genital infection. Once the virus enters the neuronal nuclei, one of two events occur: Either the virus replicates producing progeny virus which moves back to the periphery via anterograde transport process where it is released at the nerve ending to infect epithelial cells, or the virus establishes a nonreplicating persistent state referred to as latency.<sup>53</sup> In latently infected neurons the virus remains largely quiescent, except for transcription of a small region of the genome that encodes an mRNA referred to as the latency associated transcript, or LAT.<sup>54,55</sup> Recurrent HSV infections occur when the latent virus periodically reactivates, resulting in viral production and transport to the periphery where the progeny virus are released from the nerve endings to replicate further in epithelial cells.<sup>53,56</sup> Both the primary and recurrent infections can be symptomatic, characterized by the development of typical herpetic vesicles and ulcers, but more often the recurrent infections are asymptomatic, with virus replication in epithelial cells causing no apparent disease but resulting in virus shedding, which can be transmitted to a susceptible host.<sup>57,58</sup> While it is recognized that LAT is involved in the reactivation from latency, the mechanisms responsible for the establishment, maintenance, and reactivation from latency are unknown. Reactivation from the latent state and the development of recurrent infections occur despite the presence of a full range of humoral and cellular immune responses that develop following the primary infection. The development of recurrent infections is probably facilitated by a variety of immune evasion genes encoded by the virus, including a virus-encoded Fc receptor that leads to resistance to antibody-dependent cell-mediated cytotoxicity (ADCC) and an ICP47 gene product that inhibits human leukocyte antigen (HLA)-mediated viral peptide expression and recognition by cytotoxic T cells.<sup>59–63</sup>

## DIAGNOSIS

With the possible exception of herpes labialis, the clinical diagnosis of most HSV infections should be confirmed by laboratory testing. While most clinicians feel confident that they can accurately diagnose common HSV infections such as genital herpes, recent studies have shown that the accuracy of clinical diagnoses is poor even for experienced clinicians.<sup>64,65</sup> Four types of laboratory tests are available to help confirm the diagnosis, including viral culture, viral antigen detection, viral nucleic acid detection, and viral serology. For three of the four laboratory tests (culture, antigen detection, and nucleic acid detection), a lesion must be present in order to obtain the test sample. Serology may be useful in some cases when patients are evaluated after lesions have resolved. The gold standard for HSV diagnosis remains viral isolation by cell culture. Inoculation of fibroblast cell cultures with vesicular or cerebrospinal fluid (CSF) leads to rapid cytopathic change (24 to 48 hours) indicative of alphaherpesvirus infection (HSV-1, HSV-2, VZV). In general, HSV infection leads more consistently and rapidly to cytopathic change than does VZV. However, clear distinctions among HSV-1, HSV-2, and VZV can be made by the use of direct immunofluorescence using commercially available fluorescent-labeled virus-specific antibodies.

Results of positive tests are typically available within five days and negative results within six days.<sup>66</sup> Detection of HSV antigen by enzyme immunoassay (EIA) is a less sensitive alternative to viral culture and nucleic acid detection, with sensitivities in the range of 65% to 81% compared to culture and PCR.<sup>67,68</sup> The Tzanck test, the cytologic examination of Wright-Giemsa-stained smears of scrapings from the vesicle base to detect multinucleated giant cells with intranuclear inclusions, should not be used due to its poor sensitivity.<sup>69</sup> Detection of HSV DNA by PCR is not widely available but is the preferred method for examining cerebrospinal fluid and is finding increasing use for the diagnosis of mucocutaneous HSV infections. In addition to greater sensitivity, test results may be available within 24 to 48 hours.<sup>66,68,70–72</sup> Serology may be useful in confirming the clinical diagnosis of a recent illness when lesions are no longer present. Serologic detection of HSV-specific immunoglobulin M (IgM) is generally not useful. The tests are insensitive, and recurrent HSV infection can result in an anamnestic IgM response. For the HSV-seronegative patient, seroconversion by comparison of paired acute and convalescent serum samples is evidence of a recent infection. Increasing titers of virus-specific IgG are not useful in establishing the diagnosis of a recent infection as titers can vary widely in response to recurrent infections. Detection of HSV-2-antibodies in an adolescent or adult is a biomarker for genital herpes. Cases of suspected genital herpes can be confirmed by detection of HSV-2-specific antibodies using type-specific serological tests that have recently become available commercially. One caveat to remember is that many cases of genital herpes are due to HSV-1, and hence the HSV-2 type-specific serological tests will not be useful in these cases. Clinicians need to be aware that several FDA-approved HSV antibody tests claim to be type-specific but are remarkably inaccurate. The only type-specific serological tests with acceptable performance characteristics are those based on differences in the HSV-1 and HSV-2 glycoprotein G.<sup>73,74</sup>

## TREATMENT AND PROGNOSIS

Several drugs have proven effective in the treatment of various herpes simplex virus infections.<sup>75</sup> Intravenous acyclovir is the drug of choice for life-threatening HSV infections and HSV encephalitis. Oral herpes infections in the immunocompetent host have been successfully treated with oral acyclovir and its more bioavailable prodrug, valaciclovir, as well as a related nucleoside analog, famciclovir. Recurrent herpes labialis can also be treated with topical acyclovir and penciclovir and *N*-docosanol, an over-the-counter treatment. A variety of topical preparations have been used in the management of ocular herpes including acyclovir, trifluridine, idoxuridine, and vidarabine. Acyclovir-resistant strains of HSV have been documented in immunocompromised patients but are very rare in patients with an intact immune system.<sup>76</sup> Foscarnet and cidofovir have been successfully used in treatment of acyclovir-resistant HSV disease.<sup>77</sup> However, foscarnet-resistant HSV has been documented in patients with AIDS.<sup>78</sup> Antiviral drugs are useful in the treatment of primary and recurrent HSV infections, and daily suppressive use has proven effective in preventing recurrent oral and genital HSV infections. Latent infection is not altered by treatment with any currently available drug, and when suppressive therapy is discontinued

most patients return to a pretreatment recurrence pattern. All life-threatening HSV infections require treatment, and most experts feel that all first episode cases of genital herpes should be treated with an oral antiviral drug.

## PREVENTION AND CONTROL

Unfortunately, because of the high rate of clinically inapparent infections and healthy carrier states, hygienic measures are not very effective in prevention of HSV infections. However, patients with extensive mucocutaneous disease should be isolated as secretions and contact with lesions may result in transmission. Condom use has been shown to reduce, but not eliminate, the risk of genital HSV transmission.<sup>79,80</sup> A recent landmark study has shown that suppressive oral valaciclovir therapy (500 mg daily) can also significantly reduce, but not eliminate, the risk of transmission of genital HSV-2 infection among monogamous heterosexual couples.<sup>81</sup> Evidence suggests that cesarean delivery will reduce but not eliminate the risk of maternal-fetal transmission for women with active genital herpes at term.<sup>82</sup> This strategy is not without its consequences since it is estimated that four mothers die from cesarean-related complications for every seven babies prevented from developing fatal neonatal HSV infection.<sup>83</sup> An alternative but as yet unproven strategy is the use of an oral anti-HSV drug by women with a history of genital herpes for the final four weeks of gestation. The rationale is to prevent symptomatic recurrences and asymptomatic shedding at term and thereby reduce the risk of maternal-infant transmission. This strategy has been shown to reduce symptomatic and subclinical recurrences in the pregnant woman and to reduce the need for cesarean delivery for active genital herpes. The safety of such therapy in the fetus/newborn and its effectiveness in preventing neonatal herpes has not been established.<sup>84–86</sup> While there have been unsuccessful attempts to develop an effective HSV vaccine for over 60 years,<sup>87</sup> the recent success of an HSV glycoprotein vaccine in protecting women against acquiring genital herpes suggests that the development of a safe and effective HSV vaccine is feasible.<sup>88</sup> Further development of the HSV-2 glycoprotein D vaccine is under way.

## ■ Varicella-Zoster Virus

### AGENT

The transmissible agent was demonstrated first in the vesicle fluid of varicella.<sup>89</sup> The connection between varicella and zoster was made by noting varicella among children exposed to family members with zoster.<sup>90</sup> Varicella was induced in susceptible children by inoculation with fluid from zoster lesions.<sup>91</sup> Viruses isolated from varicella and zoster were later shown to be identical biologically, antigenically, and genetically.<sup>92,93</sup> The VZV genome is the smallest of the known human herpesviruses and consists of double-stranded DNA 125 kb in size with approximately 70 genes.<sup>94</sup> Large portions of the genome are colinear with the HSV-1 genome.<sup>95</sup> The three most abundant viral envelope glycoproteins, gB, gE, and gH, likely are involved in infectivity since they are major targets of neutralizing antibodies. Antigenic similarity

between HSV-1 gB and VZV gB leads to serologic cross-reactivity.<sup>96</sup>

## EPIDEMIOLOGY

Humans are the only known natural host for VZV, which is associated with two forms of illness—a primary form known as varicella (chickenpox) and a secondary form known as herpes zoster (shingles). VZV is a highly contagious infection spread usually from airborne infectious oral or respiratory secretions or sometimes through direct transfer from skin lesions or via maternal-fetal transmission. Secondary attack rates in susceptible household contacts exceed 85%.<sup>97</sup> In temperate climates, infection rates show a marked seasonal variation, with epidemics in late winter and early spring. In contrast, no seasonal variation is seen in tropical climates. The reasons for this marked difference are not clear, although it has been suggested that heat, humidity, and lack of increased exposure to virus within confined spaces during the winter months may account for some of the difference. In rural India, despite close quarters, unexpectedly low rates of household transmission were documented.<sup>98</sup> In Singapore, varicella has occurred in two very large epidemics separated by 23 years.<sup>99</sup> Although asymptomatic primary infection is rare, serologic studies suggest that subclinical reinfection is common.<sup>100</sup> Rarely, immunocompetent patients may experience second episodes of varicella.<sup>101</sup> Varicella in temperate climates most often presents in preschool and school-age children less than 10 years of age with the highest incidence in the 3- to 6-year-old group.<sup>102</sup> Despite the prevalence of varicella in childhood, some people in temperate climates do reach adulthood without exposure: A study of military recruits in the United States in the prevaccine era showed that 8% of recruits are seronegative, with a slightly higher seronegative rate in nonwhites and a much higher seronegative rate (20%) in recruits enlisting from outside the United States.<sup>103</sup>

## DISEASE

Following a 10- to 21-day (typically 14- to 16-day) incubation period, a prodrome of fever, headache, and malaise is followed 24 to 36 hours later by a diffuse maculopapular rash (Plate 57-1C). In the very young, the prodrome is often unrecognized. The rash is progressive, with successive crops at different stages occurring over a 2- to 7-day period, followed by complete healing within 20 days. The stages of the lesions are successively as follows: macular, papular, vesicular, pustular, and crusting. A hallmark of varicella is the simultaneous presence of lesions at various stages. The rash preferentially involves the trunk, with relative sparing and later involvement of the face and extremities. Oropharyngeal lesions may be seen. In normal, previously healthy children, the disease is generally benign and self-limiting, with the most common complication being secondary bacterial infection of skin lesions. Scarring is another common complication. Neurologic complications include encephalitis and acute cerebellar ataxia.<sup>104</sup> Varicella encephalitis with an incidence of 0.1% typically presents with headaches, seizures, altered thought patterns, and vomiting, with a mortality rate of 5% to 20%. Acute cerebellar ataxia is less common (0.025% incidence) than encephalitis and typically presents within 1 week of the rash

with ataxia, vomiting, altered speech, vertigo, and/or tremor, with resolution within 2 to 4 weeks.

In immunodeficient or malnourished children not treated with intravenous acyclovir, the mortality rate ranges from 15% to 18%.<sup>105</sup> These cases are characterized by dissemination, with pneumonia, myocarditis, arthritis, hepatitis, hemorrhage, and encephalopathy (cerebellar ataxia is most common). Superinfection of skin lesions with *Staphylococcus aureus* or *Streptococcus pyogenes* may lead to pyoderma, impetigo, erysipelas, nephritis, gangrene, or sepsis. In the Central American tropics, varicella in young, malnourished children may be complicated by severe diarrhea.

Adults tend to have more severe disease than children, with a 15-fold increase in mortality. Adult-onset varicella is more often complicated by pneumonitis and encephalitis, with clinically significant pneumonitis in up to 15% of cases. In the prevaccine era, approximately 4% of normal adults in the United States (temperate climate) were VZV seronegative and therefore susceptible to adult-onset varicella.<sup>106</sup> In contrast, in the tropics a much higher percentage of adults is VZV seronegative and therefore susceptible to adult-onset varicella. Persons from tropical areas who relocate to temperate areas are at risk of developing adult-onset varicella, especially if in contact with young children. Maternal varicella in early gestation leads rarely to the congenital varicella syndrome characterized by skin defects, atrophy of extremities, and autonomic nervous system dysfunction.<sup>107,108</sup> Maternal varicella in late gestation may lead to neonatal varicella, with a mortality rate as high as 30% in untreated infants.<sup>109,110</sup>

Recurrent VZV infection is manifest as herpes zoster (shingles), a disease usually seen in adults over 50 years of age. Data suggest racial differences in the risk of developing zoster, with white elderly more at risk than black elderly.<sup>111</sup> Zoster may also rarely occur in childhood. Zoster in immunocompromised patients may be quite protracted and severe. The increased incidence of zoster in the aged as well as in immunocompromised patients is likely due to decreased anti-VZV cell-mediated immunity.<sup>112,113</sup> Interestingly, there is evidence that exposure of at-risk seropositive persons to varicella protects against development of zoster, presumably by boosting their immune response.<sup>114</sup> After primary infection, VZV (like HSV) persists in the latent state within spinal and cranial nerve ganglia. Nonspecific stimuli such as stress, immunodeficiency, or malignancy may induce activation of latent virus with involvement of the skin in the nerve distribution supplied by the affected ganglion. Herpes zoster presents after a 3- to 4-day prodrome of fever, malaise, and gastrointestinal disturbance as a painful cutaneous vesicular eruption in a dermatomal distribution (Plate 57-1D). The rash is usually unilateral and along one dermatome only. In severe cases, the eruption may be more generalized and varicelliform. The vesicles heal within 5 days, but postherpetic neuralgia may commence. Postherpetic neuralgia, seen in up to 50% of patients over 50 years old, is defined as constant or intermittent debilitating pain of more than one month's duration in the area of the involved dermatome. Infection of the eye, ear, and throat may occur if ophthalmic, trigeminal, or geniculate ganglia are involved. Herpes zoster ophthalmicus is a particularly serious condition, which if untreated may lead to blindness. The Ramsay-Hunt syndrome is defined as a triad of involvement of the external auditory meatus, loss of taste in

the tongue, and ipsilateral facial palsy. Involvement of the spinal cord may lead to weakness or cranial nerve palsy. The risk of encephalitis is increased in the elderly with cranial nerve involvement and in AIDS patients. Postzoster encephalitis may present in one of three forms: infarcts due to large-vessel vasculitis, multifocal leukoencephalopathy, and ventriculitis.<sup>115</sup>

## **PATHOGENESIS AND IMMUNITY**

As is characteristic of alphaherpesviruses, VZV replicates rapidly in a restricted range of cells in vitro with rapid cell death. VZV replicates best in human diploid fibroblasts but also infects primary human keratinocytes.<sup>116</sup> A live attenuated vaccine strain (OKa) is propagated in WI-38 and MRC-5 diploid fibroblast lines. In cell culture, the virus remains largely cell associated with little release of infectious virus.<sup>117</sup> However, cell-free virus can be obtained by sonication of infected cultures. Infection induces the formation of multinucleated cells with eosinophilic intranuclear inclusions seen both in vitro and in vivo. Transmission occurs mainly through respiratory spread, and viremia disseminates the virus to mucocutaneous sites, visceral organs, and the peripheral nervous system. Latent infection is established in cranial, dorsal root, and autonomic ganglia.<sup>118–124</sup> The cell specificity of latent virus was previously controversial, but it is now widely agreed that latent VZV primarily resides in neurons and to a much lesser extent in non-neuronal satellite cells.<sup>125</sup> Evidence suggests that at least five viral genes are transcribed during latency, and unlike HSV latency, transcription from the latent VZV genome results in viral protein expression.<sup>126</sup> Like HSV, latent VZV can reactivate, albeit very rarely, to cause recurrent infection (e.g., zoster or shingles). Unlike HSV, reactivation of VZV can result in neuronal injury that causes a prolonged pain syndrome referred to as postherpetic neuralgia.<sup>127</sup>

## **DIAGNOSIS**

The clinical diagnosis of varicella in childhood, now that variola (smallpox) has been eradicated, is not usually difficult. The rash is quite characteristic and only rarely needs to be differentiated from enteroviral exanthem, *S. aureus* infection, drug reactions, contact dermatitis, and disseminated HSV-1 infection. Diagnosis by culture of vesicle fluid is less sensitive than for HSV or CMV and may take 7 days. This method has been supplanted by the more rapid and sensitive shell vial method, which gives results in 1 to 3 days. Very rapid, sensitive, and specific detection may supplant culture-based systems in the near future as multiplex PCR assays become more widely available.<sup>128</sup> Scrapings of the base of the vesicles reveal multinucleated giant cells with intranuclear inclusions, which cannot reliably be differentiated from HSV. However, immunofluorescence on cultures or scrapings utilizing virus-specific antibodies can differentiate between HSV-1, HSV-2, and VZV. Serologic detection of IgM and a high titer or greater than fourfold rise in IgG anti-VZV antibody may be useful in some cases. Detection of IgM may signify primary infection (chickenpox), while either a high titer or fourfold rise in IgG titer indicates recurrence. However, increased IgM may also be seen in recurrence. The clinical diagnosis of herpes zoster in adults is

also not usually difficult given the characteristic dermatomal pattern of involvement.

## TREATMENT AND PROGNOSIS

Although vidarabine and interferon- $\alpha$  have been used in the treatment of severe VZV infection, acyclovir is the drug of choice.<sup>129</sup> Acyclovir is most effective in severe VZV infection if administered intravenously (IV) within 24 hours after the rash develops.<sup>130</sup> Oral acyclovir treatment of otherwise healthy children with chickenpox should be considered, particularly in adolescents and secondary household contacts, although the benefit is modest.<sup>131–134</sup> Due to the detection of acyclovir-resistant strains in patients with AIDS, foscarnet therapy should be considered for severe infection in this setting.<sup>135,136</sup> For herpes zoster, the drugs of choice are famciclovir and valacyclovir. Early treatment of zoster has been shown to both shorten the course of cutaneous disease and reduce the duration and severity of postherpetic neuralgia.<sup>137</sup> Topical steroids may also be useful in herpetic uveitis and keratitis. Painful zoster may be treated with wet compresses and analgesics containing codeine. Gabapentin, a structural analogue of the neurotransmitter gamma-aminobutyric acid, is useful in the management of postherpetic neuralgia.<sup>138</sup> Antihistamines may be useful to ameliorate the intense pruritus of varicella in childhood. A live attenuated vaccine (OKa) is licensed in the United States for routine use in children and susceptible adults.<sup>139</sup> The vaccine has been shown to be safe and effective, and its widespread use has resulted in a decline in varicella cases in the United States.<sup>140</sup> The vaccine virus may induce mild varicella and is capable of reactivation with development of herpes zoster.<sup>141,142</sup> In some cases, as in patients with leukemia, two doses of vaccine are required to achieve 95% seroconversion rates.<sup>143</sup> As with other vaccines, immunization with the VZV vaccine does not always result in protection, as evidenced by numerous reports of vaccine failure.<sup>144</sup>

## PREVENTION AND CONTROL

Owing to the high prevalence of the infection in the pre-vaccine era, its high transmissibility, and the fact that infected persons are contagious 24 to 48 hours before clinical signs occur, it is difficult to prevent infection by isolation. However, reverse isolation is recommended for hospitalized patients with varicella and for children or immunocompromised adults with herpes zoster. Patients with varicella should be bathed often to prevent staphylococcal and streptococcal superinfection. Immunocompromised children, neonates born to mothers who present with varicella during the week prior to and a few days after birth, and seronegative pregnant females should be treated with varicella-zoster immune globulin (VZIG) within 96 hours of exposure.<sup>145</sup> VZIG, however, has no effect on the course of herpes zoster or on risk of reactivation.

## ■ Human Cytomegalovirus

### AGENT

Human CMV is classified as a betaherpesvirus by virtue of tropism for salivary glands; high species specificity (no natural host other than humans); and slow, nonlethal growth in

cell culture.<sup>146</sup> Of the human herpesviruses, CMV is most closely related genetically to HHV-6.<sup>147</sup> CMV virions range from 150 nm to 200 nm in diameter and may be distinguished from other herpesviruses by having a more pleomorphic envelope.<sup>148</sup> CMV has the largest genome of all herpesviruses at 230 kbp, with a large-scale genomic arrangement similar to that of HSV-1.<sup>149,150</sup> The human CMV genome has been completely sequenced and contains approximately 200 open reading frames (ORFs) and an unusually large number of repeat units.<sup>151</sup> Purified virions contain at least 30 polypeptides, including the major capsid protein (MCP, pUL86), which, unlike capsid proteins from other herpesviruses, is poorly immunogenic.<sup>152,153</sup> The major envelope glycoprotein of CMV (gB, gpUL55), which is involved in cell penetration and fusion, is the major target of neutralizing antibody, as well as an important target of the cellular immune system.<sup>154–156</sup> Sequence variation in gB has been used to define four CMV gB subtypes.<sup>157</sup> gB type 1 CMV may be more often associated with clinically significant disease in bone marrow transplant recipients.<sup>158</sup>

## EPIDEMIOLOGY

CMV is ubiquitous, with seroprevalence rates of 40% to 80% in young adults in the Western world, while in some tropical regions, such as Barbados and Tanzania, the rate approaches 100%.<sup>159</sup> No seasonal variations are described.<sup>159</sup> The vast majority of CMV infections are subclinical, but in infancy infection is often followed by a prolonged period of viral shedding.<sup>160,161</sup> Those at risk of serious infection include the fetus, the newborn, the elderly, the debilitated, and the immunocompromised. Primary infection most often occurs in young children. Low socioeconomic status, breastfeeding, and increased exposure to young children is associated with an increased rate of early childhood infection. Up to 60% of infants acquire CMV infection during the first 6 months. Perhaps the most common mode of transmission in infants is by breastfeeding.<sup>162,163</sup> At least 30% of seropositive women excrete CMV in breast milk during the first year postpartum.<sup>164</sup> Young children who attend day care and are in close contact with other children are much more likely to acquire CMV infection than children who stay home (80% vs. 20%).<sup>165</sup> Seroprevalence again increases in adolescence and young adulthood with sexual activity. Infection in this age group may be manifest as a mononucleosis syndrome with fever, fatigue, and myalgia mimicking that caused by EBV.<sup>166,167</sup> However, in contrast to EBV-induced mononucleosis, adenopathy, pharyngitis, and tonsillitis are not pronounced, and the heterophile antibody test is negative.

## DISEASE

Following primary infection, viral excretion from many sites, including saliva and urine, is prolonged, thus leading to a vast reservoir of infectious virus. However, probably owing to its unstable nature, CMV transmission requires intimate contact, as has been described in children in day-care settings or in overcrowded or unsanitary areas. CMV has also been implicated in some cases of recurrent aphthous ulcers and Behçet's disease.<sup>168</sup> However, those most at risk of serious CMV infection

are neonates and immunocompromised (post-transplant, AIDS) patients. In the United States, 1% of newborns shed CMV in the urine, thus making CMV infection the most common congenital infection. Congenital CMV infection most often follows primary maternal infection. The risk to the fetus is much less in the case of reactivated maternal infection due to the presence of a preexisting maternal immune response. Given the very high seropositivity rates in the developing world, congenital CMV is probably less common in the tropics. Approximately 1% of CMV-seronegative pregnant females will acquire a primary infection during pregnancy with a fetal infection rate of 40%, while approximately 10% of CMV-seropositive pregnant females will have a recurrent CMV infection during pregnancy with a fetal infection rate of 10%. Approximately 20% of the time, primary maternal infection leads to clinically apparent disease in the newborn, with a mortality rate of 20% to 30%. Early congenital infection often leads to fetal death or permanent neurologic damage. In fact, more than 90% of infants born with symptomatic congenital infection and up to 20% of those with asymptomatic infection later prove to be permanently neurologically impaired. The most severe form of congenital infection, cytomegalic inclusion disease (CID), is characterized by disseminated infection leading to hepatosplenomegaly, microcephaly, mental retardation, nerve deafness, thrombocytopenic purpura, and hemolytic anemia. The seriousness of congenital CMV infection is underscored by the fact that in the United States and England 0.1% of all newborns have CMV-associated residual defects (hearing loss, psychomotor retardation, blindness). Hearing loss is by far the most common neurologic deficit and is the most common cause of acquired hearing loss in U.S. children, while chorioretinitis leading to loss of vision is the second most common CMV-induced neurologic deficit.<sup>169,170</sup> Children with CID may excrete CMV in body fluids for years and therefore serve as reservoirs of infection.<sup>171</sup> Postnatal infection may follow transmission from an infected mother's cervicovaginal secretions, urine, saliva, or breast milk. Although usually asymptomatic, postnatally infected infants serve as sources of infection of children and adults. Seronegative pregnant mothers are at risk of infection from toddlers attending preschool since up to 80% may be excreting virus in saliva and urine.<sup>165</sup> Given the high rate of the CMV carrier state, CMV may also be transmitted through blood transfusion, which in the premature infant may lead to a respiratory distress syndrome and in seronegative adults to a mononucleosis syndrome. In immunocompromised patients (organ transplant, malignancy, AIDS), CMV infection may lead to severe multisystem disease with fever, pneumonitis, leukopenia, arthritis, hepatitis, retinitis, ulcerative gastrointestinal disease, and encephalitis. CMV is probably the most common post-transplant infection, with viral shedding in nearly 100% of all patients.<sup>172</sup> The role of CMV infection in transplant rejection is unclear; although it has been implicated as a cofactor in chronic liver allograft rejection, it apparently plays no role in acute cardiac transplant rejection.<sup>173,174</sup> CMV has been implicated in chemotherapy-induced neutropenic fevers of unknown origin.<sup>175</sup> CMV has also been implicated as a cofactor in the clinical progression of AIDS.<sup>176</sup> Recent reports of the presence of CMV within atherosclerotic vascular lesions has led to suggestions that CMV may be a cofactor in the pathogenesis of atherosclerosis.<sup>177,178</sup>

## PATHOGENESIS AND IMMUNITY

CMV gene expression can be temporally classified into three distinct phases, termed alpha (immediate early), beta (delayed early), and gamma (late). Alpha genes are expressed without prior protein synthesis and are largely involved in transcriptional transactivation. Beta genes are dependent upon prior alpha gene expression and encode proteins required for DNA replication. Gamma genes are dependent upon prior DNA replication and encode virion structural proteins. CMV replication is slow, with 42 to 72 hours required before progeny virus is recovered.<sup>179</sup> Like all betaherpesviruses, CMV exhibits a highly restricted host cell range *in vitro*. Primary fibroblasts from skin and lung are most permissive, while undifferentiated or transformed cells are nonpermissive.<sup>180</sup> Unlike the alphaherpesviruses, CMV stimulates cellular molecular synthesis and cell enlargement (cytomegalia).<sup>181,182</sup> Large characteristic nucleocapsid inclusions form within the nucleus and the cytoplasm.<sup>183</sup> In primary infection and in healthy carriers, CMV appears to replicate in salivary gland epithelium and may also be found in renal tubular cells and peripheral blood monocytes.<sup>184–187</sup> However, in the immunocompromised host (fetus, newborn, AIDS patients, transplant recipients), CMV may replicate in virtually any organ.

## DIAGNOSIS

Congenital CMV infection should be differentiated from congenital toxoplasmosis, rubella, herpes simplex, and syphilis. Clinically, congenital toxoplasmosis closely resembles CID, but unlike CMV the cerebral calcifications are usually scattered rather than confined to the periventricular areas. Since the introduction of the rubella vaccine in 1969, congenital rubella has become rare in the developed world, yet remains a problem in the tropics. Congenital rubella is more often associated with glaucoma, cataracts, microphthalmia, and cardiac malformations (especially patent ductus arteriosus). Congenital herpes simplex is rare and probably leads in most cases to fetal demise. Neonatal disease is most often acquired at birth from mothers with herpes genitalis and usually, but not always, presents with a characteristic vesicular rash. Detection of virus-specific IgM in the affected neonate is usually sufficient to confirm the diagnosis. Newborns with congenital syphilis commonly present with a characteristic complex of rhinitis, diffuse maculopapular desquamative rash, and osteochondritis. CMV mononucleosis in older children and young adults may be differentiated from EBV mononucleosis by a combination of clinical features (higher fever, absent or mild pharyngitis, and adenopathy) and a negative heterophile antibody test. Although more specific, viral serology for mononucleosis is seldom required. CMV hepatitis is usually milder than disease due to hepatitis A, B, or C. Elevated CMV-specific IgM or a fourfold rise in IgG titers using paired acute and convalescent serum samples are useful in normal adults to detect active CMV infection. CMV culture is most useful in cases in which serology is unreliable, that is, in congenital infection and in the post-transplant and AIDS setting. Amniotic fluid culture may be appropriate in some circumstances. Culture of CMV on human embryonic fibroblasts is sensitive and specific but is not a rapid test—the characteristic cytopathic effect (CPE) may take up to 2 to 5 weeks

**FIGURE 57-2** Cytomegalovirus pneumonitis. (Courtesy of Vicki Schnadig, MD, Department of Pathology, UTMB, Galveston, TX.)

to become apparent. More rapid diagnosis is obtained with the use of shell vial cultures in which the sample is centrifuged onto a fibroblast culture and is stained on day 1 or 2 with CMV early antigen (EA)-specific fluorescein-conjugated antiserum. The shell vial assay has been shown to be more sensitive than serology in the diagnosis of infection in the neonate and immunodeficient patient.<sup>188</sup> However, because of the high rate of asymptomatic viral shedding and reactivation, interpretation of culture and serology results must be carefully evaluated in each specific clinical setting. PCR-based tests provide very rapid, sensitive, and specific detection and will likely eventually supplant culture-based systems. PCR was shown to be more sensitive in detection of CMV from urine than either conventional or shell vial culture.<sup>189</sup> However, the detection of CMV DNA by PCR does not correlate well with CMV disease—in one study, the positive predictive value of CMV PCR for disease in transplant patients was only 27.8%.<sup>190</sup> It is likely that serial quantitative PCR assays in susceptible populations will lead to improvements in the positive predictive value of the test. Although CMV has been classified by gene sequence analysis of the CMV major envelope glycoprotein gB into four subtypes, a recent PCR study failed to detect subtype differences in clinical outcome or viral load in renal transplant patients.<sup>191</sup> CMV infection in tissue is characterized by the presence of large intranuclear inclusions in infected cells (Fig. 57-2).

### TREATMENT AND PROGNOSIS

Ganciclovir and foscarnet have been used both as CMV prophylaxis and as treatment of severe infection in the post-transplant and AIDS settings. The renal toxicity of foscarnet and the myelotoxicity of ganciclovir sometimes limit their use. In CMV retinitis, both foscarnet and cidofovir are effective. Ganciclovir, cidofovir, and foscarnet resistance has been shown to be due both to viral DNA polymerase mutations, and, in the case of ganciclovir, also to poor phosphorylation.<sup>192–195</sup>

### PREVENTION AND CONTROL

The importance of prevention of primary CMV infection in pregnant women is difficult to overemphasize. CMV is

probably the most common congenital infection worldwide. Seronegative pregnant women exposed to toddlers, especially those with a high level of contact with other toddlers, as in the day-care setting, are at risk of acquiring primary CMV infection with fetal transmission and development of congenital CMV disease, a serious disease which leads in most cases to either fetal loss or a child with permanent neurologic damage. Simple behavioral changes by pregnant women in contact with toddlers, such as frequent handwashing and use of disposable diapers and gloves, may be quite effective in preventing infection.<sup>196</sup> In seronegative newborns and allograft recipients, the risk of post-transfusion CMV infection can be markedly reduced by administration of either leukocyte-reduced blood products or CMV-seronegative donor blood products. Subunit vaccines using the CMV major envelope glycoprotein gB and other proteins are currently under development.<sup>197</sup>

## ■ Epstein-Barr Virus

### AGENT

EBV is a human herpesvirus of the gammaherpesvirus subfamily and genus *Lymphocryptovirus*. Humans are the only known natural host for EBV, although all Old World primate species have closely related lymphocryptoviruses.<sup>198</sup> EBV was first identified as a typical herpesvirus by electron microscopy from a biopsy of endemic African Burkitt's lymphoma.<sup>199</sup> EBV was also shown to cause most cases of infectious mononucleosis.<sup>200</sup> Permanent transformed cell lines harboring EBV can be obtained from infectious mononucleosis blood and from Burkitt's lymphoma tissue.<sup>201</sup> Subsequently, the virus was shown to also be associated with a number of other human diseases, including undifferentiated nasopharyngeal carcinoma (NPC) and other lymphocyte-rich carcinomas, oral hairy leukoplakia in AIDS patients, malignant lymphoma of both B- and T-cell types, and Hodgkin's disease (HD).<sup>202–210</sup> Although in vitro only B cells appear to be efficiently infected and transformed, in vivo it appears as though the host cell range for EBV is not as restricted—not only B cells but in some cases T cells, epithelial cells, and mesenchymal cells may harbor EBV. EBV gains access to the B lymphocyte through the C3d receptor (CR2, CD21).<sup>211</sup> An EBV strain obtained from a patient with mononucleosis and used to transform marmoset B cells (B95-8) has been cloned and sequenced.<sup>212</sup> EBV DNA is 172 kb in size with several sets of repeat elements separated by unique regions containing more than 100 ORFs. Given the importance of the phenomenon of B-cell latency, a great deal of attention has been devoted to the latent genes which encode six nuclear proteins (*EBNA1–6*), three membrane proteins (*LMPI*, 2A, 2B), and two highly abundant nonpolyadenylated nuclear RNAs (*EBER1–2*). Also, there are some EBV genes with homology to human genes, including *BHRF1* (*bcl2*-like), *BCRF1* (*IL10*-like), and *BZLF1* (*jun/fos*-like).<sup>213–215</sup> It has been suggested that these genes may have been appropriated from the primate genome to provide a survival advantage to EBV-infected cells.<sup>198</sup>

### EPIDEMIOLOGY

There appear to be two distinct strains of EBV, type 1 (or A type) and type 2 (or B type), which differ in geographic

distribution, biologic properties, and genetic sequences.<sup>216,217</sup> The strains differ genetically mostly in the *EBNA2*, *EBNA3*, and *EBER* genes. Type 2 isolates transform B cells in vitro with much lower efficiency than type 1 isolates.<sup>218</sup> Although type 2 isolates are more commonly isolated from Asia, Africa, and AIDS patients, they may be recovered not infrequently from the oropharynx of normal persons from the developed world.<sup>216</sup> Although type 1 isolates are more commonly isolated from tumors, no clear difference in pathogenicity of type 1 vs. type 2 EBV is established.

## DISEASE

EBV is a human gammaherpesvirus that establishes transient lytic infection of the oropharyngeal mucosal epithelium and chronic latent infection of B lymphocytes. Infection most often occurs following contact with infectious saliva of healthy carriers or patients with infectious mononucleosis. EBV, like the other herpesviruses, has a ubiquitous distribution with an overall adult seroprevalence exceeding 90%. The high rate of seroprevalence is maintained by a large population of healthy carriers—up to 20% of healthy seropositive people in the developed world and 45% of African children excrete virus intermittently in saliva. Unlike CMV, EBV is not recognized as a common congenital or neonatal infection and has not clearly been shown to be transmitted through the genital tract. In the developing world and especially in subequatorial areas of Africa endemic for Burkitt's lymphoma, early childhood infection is the rule and is nearly always asymptomatic. Even in developed countries, many, if not most, primary infections occur in childhood and are subclinical. Primary infection as it occurs in adolescents and young adults classically presents as infectious mononucleosis. Because of the high rate of childhood infection in the tropics, infectious mononucleosis is seldom encountered. Although EBV accounts for the majority of cases of infectious mononucleosis, similar syndromes are caused by CMV, *Toxoplasma*, and viral hepatitis. EBV-associated mononucleosis typically follows an incubation period of 1 to 2 months and is characterized by several weeks of fever, pharyngitis, malaise, headache, and posterior cervical lymphadenopathy. Laboratory features include atypical lymphocytosis, positive heterophile antibody test (which may be negative in children), positive IgM anti-viral capsid antigen (VCA), and elevated IgG anti-VCA. Most of the atypical lymphocytes in peripheral blood express an immunophenotype consistent with activated CD8-positive cytotoxic T cells, with a lesser increase in natural killer (NK) cells.<sup>219</sup> Other manifestations include mild hepatitis, splenomegaly, encephalitis, polyneuritis, pneumonia, ampicillin-induced rash, and a variety of autoimmune phenomena. In the vast majority of cases, complete spontaneous recovery without recurrence follows. Rarely, however, probably associated with immunodeficiency, either a fatal hemophagocytic syndrome with marrow failure or malignant B-cell lymphoma may intervene. EBV, unlike the other human herpesviruses, with the possible exception of HHV-8, is clearly oncogenic and as such is classically associated with at least three human malignancies—endemic Burkitt's B-cell lymphoma, post-transplant B-cell lymphoma, and NPC—and more loosely associated with other human malignancies—HD, lymphocyte-rich carcinoma, gastric adenocarcinoma,<sup>220,221</sup> smooth muscle

tumors,<sup>222,223</sup> some T-cell lymphomas, and other B-cell lymphomas (AIDS-associated, sporadic nonendemic Burkitt's, primary CNS lymphoma).<sup>224</sup> EBV is also associated with Duncan's disease, a fatal infectious mononucleosis-like illness in boys with the rare X-linked lymphoproliferative syndrome.<sup>225</sup> HIV-positive patients and rarely post-transplant patients develop a benign wartlike lesion on the lateral borders of the tongue called oral hairy leukoplakia, which is productively infected with EBV.<sup>206</sup>

Endemic Burkitt's lymphoma is the most common childhood malignancy in the central equatorial regions of Africa in areas ravaged by holoendemic falciparum malaria.<sup>226</sup> Endemic Burkitt's lymphoma is also found in coastal Papua New Guinea, another area ravaged by holoendemic falciparum malaria.<sup>201</sup> It usually presents as a rapidly enlarging tumor of the jaw or abdomen in children. The tumor is very aggressive and fatal without treatment. However, due to the rapid growth rate, the tumor is exquisitely sensitive to chemotherapy. Treatment with cyclophosphamide, vincristine, cytarabine, and intrathecal methotrexate leads to a 93% clinical remission rate and 63% 2-year disease-free survival rate. Prospective serologic studies indicate that children who develop Burkitt's lymphoma have elevated EBV antibody titers (higher than age-matched controls) months to years prior to tumor development. The tumor has a highly characteristic "starry-sky" histologic appearance with monotonous sheets of mitotically active lymphoblasts interspersed with debris-laden phagocytic histiocytes (Fig. 57-3). The tumor cells invariably contain a chromosome translocation involving the *c-myc* gene on chromosome 8 and an immunoglobulin gene on chromosome 2, 14, or 22: t(8;14), t(2;8), or t(8;22). Sporadic Burkitt's lymphoma is a tumor that usually presents as an abdominal mass in older children and adults in nonendemic areas. Despite sharing an identical histologic appearance and similar *c-myc* translocations with endemic Burkitt's lymphoma, sporadic Burkitt's is uncommonly (approximately 20%) associated with EBV.<sup>227</sup> The *c-myc* breakpoints seen in endemic Burkitt's are most often found far upstream of *c-myc*, while those seen in sporadic Burkitt's lymphoma are most often found within, or close to, the *c-myc* gene.<sup>228</sup>

NPC is a disease of adults with a peak incidence at age 50 to 54 years and a male predominance (3:1). NPC is one of the

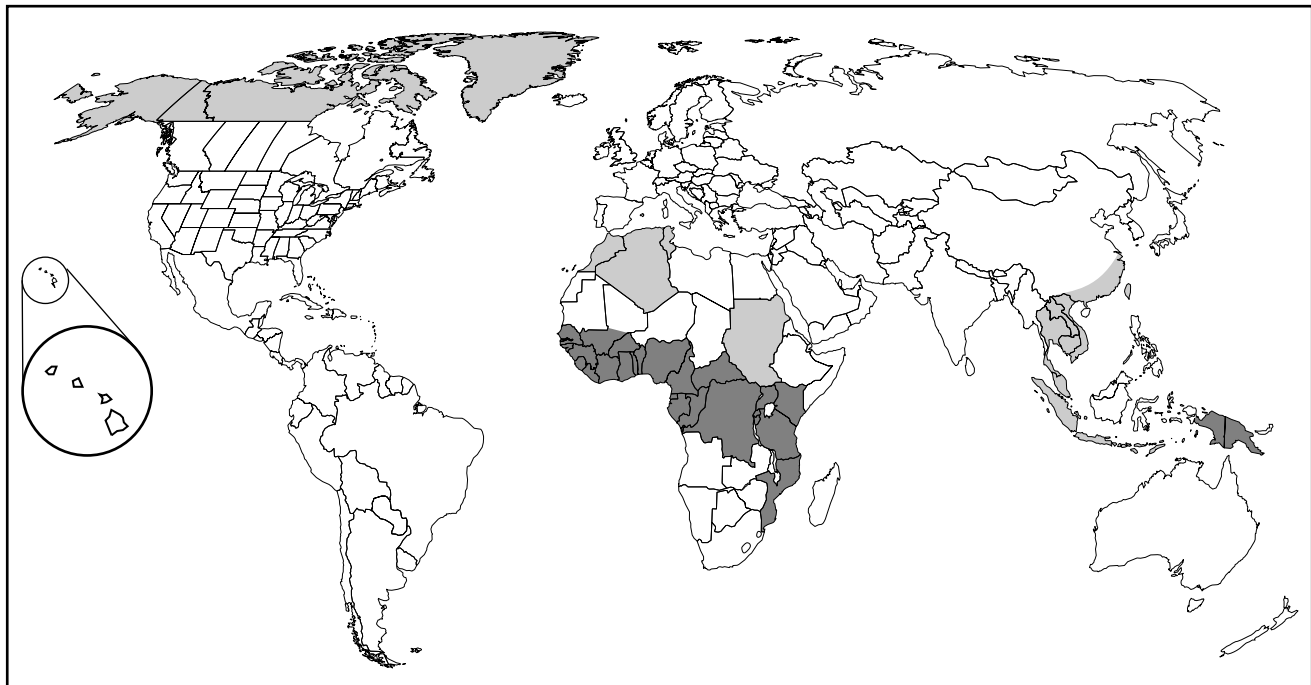

FIGURE 57-3 Burkitt's lymphoma.

### Nasopharyngeal Carcinoma and Endemic African Burkitt's Lymphoma

- Endemic African Burkitt's Lymphoma
- Nasopharyngeal Carcinoma

most common malignant tumors in the southern Chinese, especially Cantonese, and has a lower incidence in North African Arabs and in Aleuts. The endemic nature of NPC suggests that either genetic or environmental factors may influence risk. Genetic studies of the Singapore Chinese population have suggested linkage to HLA haplotypes A2Bw46 and A19B17.<sup>229</sup> Environmental studies have suggested an increased risk with consumption of salted fish during infancy and occupational exposure to smoke or dust.<sup>230–233</sup> Salted fish from southern China and Greenland, as well as preserved foods from Tunisia, all areas with endemic NPC, contain a significant amount of volatile nitrosamines.<sup>234</sup> The role of environmental factors is underscored by the fact that the incidence of NPC in second-generation immigrant Chinese in North America is lower than in the first generation.<sup>235</sup> Patients may present with nasal stuffiness, nosebleeds, ear pain, hearing loss, facial pain, difficulty swallowing, taste changes, and cervical adenopathy. There are three histologic subtypes of NPC: well-differentiated squamous cell carcinoma, nonkeratinizing carcinoma, and lymphocyte-rich undifferentiated carcinoma with EBV in situ positive tumor cells (Plate 57-2). The lymphocyte-rich undifferentiated form of NPC is both the most common (80% of cases) and the most consistently EBV-associated subtype (100% of cases) (see Plate 57-2), whether occurring in endemic areas or not.<sup>204,236</sup> EBV gene expression is limited to *EBER1/2*, *EBNA1*, *LMP1/2*, and unusual transcripts from the *Bam A* region.<sup>222,237</sup> *LMP1* gene expression has been shown to induce phenotypic changes and transformation in epithelial cells and is therefore likely to play a role in NPC pathogenesis.<sup>238–241</sup> Analysis of DNA from NPC has revealed deletions on the short arm of

chromosome 3, which may be sites of tumor suppressor genes.<sup>242</sup> Overexpression of wild-type *p53* and *bcl-2* in NPC cells also suggests a role for these cellular genes in NPC pathogenesis.<sup>243,244</sup> EBV is also associated in NPC-endemic areas, especially Southeast Asia, with carcinomas with undifferentiated NPC-like histologic features arising in the thymus, salivary glands, and lung. However, unlike NPC, similar tumors arising in nonendemic areas are seldom EBV associated.

Organ transplant patients are at increased risk for the development of EBV-associated post-transplant B-cell lymphoproliferative disorders (PTLDs).<sup>245,246</sup> The risk varies with the organ transplanted, with the highest risk associated with HLA-mismatched T cell-depleted bone marrow transplants (24%) and the lowest risk associated with undepleted bone marrow and renal transplants (1%). This organ-specific risk is likely a reflection of the various degrees of induced immunosuppression required to prevent graft rejection.<sup>247</sup> Another important risk factor for PTLD is EBV serologic status, with EBV-seronegative patients at a 76-fold increased risk compared with EBV-seropositive patients.<sup>248,249</sup> The increased risk of PTLD in the pediatric age group reflects the relatively low seropositivity rate of children in the developed world. The clinical presentation of PTLD is highly variable but may present in the early post-transplant period, particularly in seronegative patients, as an infectious mononucleosis-like illness with fever, lymphadenopathy, and fatigue; in the late post-transplant period as a solid tumor, often extranodal, with involvement of the gastrointestinal tract, CNS, or allograft; and in heavily immunosuppressed patients as a fulminant sepsis-like presentation with multiorgan involvement.<sup>250</sup> Pathologically, PTLD is heterogeneous and ranges from diffuse

polymorphous lymphoid hyperplasia to monomorphic large B-cell lymphoma (Fig. 57-4). B-cell clonality studies indicate heterogeneity with polyclonal, oligoclonal, and monoclonal B-cell populations.<sup>251,252</sup> The EBV gene expression pattern is very similar to that seen in vitro in lymphoblastoid cells with limited lytic activity.<sup>253,254</sup> Although limited cytogenetic studies have failed to identify a characteristic chromosomal abnormality in most cases, some monomorphic cases do contain Burkitt-like *c-myc* rearrangements.<sup>254</sup> PTL has been subclassified into three clinicopathologic types—a polyclonal plasmacytic type without cytogenetic abnormalities, which regresses following immunorestitution; a monoclonal polymorphic type without cytogenetic abnormalities, which regresses following either immunorestitution or chemotherapy; and a monoclonal immunoblastic lymphoma or myeloma with mutations of *c-myc*, *N-ras*, or *p53*, which does not respond to therapy.<sup>255</sup>

HD is a common malignant lymphoproliferative disease with a worldwide distribution. First described by Thomas Hodgkin from postmortem records of adults with massive peripheral lymphadenopathy, the disease continues to confound efforts to fully understand the process.<sup>256</sup> The incidence of HD is bimodal, with an early peak in the developed world in late adolescents and early adults that is shifted to childhood in the developing world and a late peak beyond the age of 50 years.<sup>257</sup> This pattern of incidence, as well as other epidemiologic data, had suggested that an infectious agent is involved. HD usually presents with peripheral lymphadenopathy often confined to the neck and sometimes accompanied by a mediastinal mass or splenomegaly, or both. Patients may also present with a variety of nonspecific systemic findings including fever, weight loss, anemia, and malaise. Unlike the non-Hodgkin's lymphomas, HD rarely involves extranodal sites other than the spleen and bone marrow.

Prognosis and treatment of HD are heavily dependent on determination of the stage of the disease. The Ann Arbor staging system comprises stages I to IV based on anatomical extent, followed by an A (without) or B (with) for the presence of systemic findings.<sup>258</sup> Treatment ranges from surgical excision and limited radiotherapy in stage I disease to combination radiotherapy and multiagent chemotherapy in stage IV disease. HD is usually classified as one of four histologic types—nodular sclerosis, mixed cellularity, lymphocyte predominant, and

FIGURE 57-5 Hodgkin's disease.

lymphocyte depleted—which differ not only in the composition of the reactive background but also in the type of Reed-Sternberg (RS) cells.<sup>259</sup> Although there is some association of histologic type with prognosis, this association may not be independent of stage. The histology of HD is puzzling—like no other malignant tumor, the malignant RS cells are usually in the distinct minority, while most of the cells within the tumor are not malignant and include T cells, histiocytes, granulocytes, and fibrous stromal cells (Fig. 57-5). The RS cell itself is also a mystery. Unlike the cells of most tumors these cells do not morphologically resemble any known normal cell. The lack of resemblance is more than morphological—the immunophenotype and genotype of the classic RS cell do not correspond to those of any known normal cell. The RS cell characteristic of lymphocyte-predominant HD, the L&H or popcorn cell, has been shown to have the phenotypic and genotypic characteristics of a B lymphocyte, while the classic RS cells characteristic of the other histologic types of HD remain uncertain. While PCR analysis of single RS cells has led to varied results, in one report clonal immunoglobulin rearrangements consistent with a monoclonal B-cell origin for the RS cells were found in three of three patients tested.<sup>260–262</sup>

EBV has been associated with most cases of non-lymphocyte-predominant HD by PCR and shown to be localized within the RS cells by in situ hybridization.<sup>207</sup> As EBV primarily infects B cells, it is curious that it is the classic RS cells rather than the B-cell L&H RS cells of lymphocyte-predominant HD which are EBV-positive. This may be explained by the fact that EBV infection of B cells is associated with downregulation of the expression of the B-cell antigen CD20 commonly used in tissue sections to detect B-cell phenotype.<sup>263</sup> The fact that EBV within a given case is clonal supports the notion that the virus is not merely a passenger virus but is playing an important role in growth of the RS cells.<sup>208,264</sup> EBV gene expression in RS cells is restricted to *EBER1/2*, *LMP1*, and *EBNA1*, an EBV latency pattern termed type II shared with that of NPC. A 30-bp deletion within the EBV *LMP1* gene, which is present in a high percentage of EBV-positive HD cases, was suggested to be of pathogenetic significance.<sup>265</sup> However, further studies have cast doubt on this hypothesis since the deletion may also be found in EBV isolates from normal persons.<sup>266</sup> EBV is clearly not essential to the development of all cases of classic HD because up to 40% of these

FIGURE 57-4 Post-transplant lymphoma.

cases are EBV negative.<sup>267</sup> The association of EBV with HD varies with age, geographic location, and histologic subtype. HD is more strongly associated with EBV before the age of 15 and after the age of 50 years.<sup>268,269</sup> The EBV association is stronger in the developing world than in the Western world and is more commonly associated with mixed cellularity type and less commonly with the nodular sclerosis type.<sup>270,271</sup> Also, EBV does not play an important role in the rare familial form of HD.<sup>272</sup> The role of EBV does appear to be magnified in cases in which the host is immunocompromised, since HD in the setting of AIDS is nearly always EBV positive, suggesting that poor control of EBV infection may allow EBV to play a role. Although the risk of developing HD is significantly increased in patients with a past history of infectious mononucleosis, more recent studies indicate that those HD patients with a history of infectious mononucleosis were paradoxically less likely to develop EBV-associated HD.<sup>273,274</sup> Another puzzle is that no EBV-specific cellular immune response is seen in EBV-positive HD tissues from presumably immunocompetent persons, while intact responses are seen in EBV-negative cases.<sup>275</sup> It has been suggested that inhibitory cytokines such as interleukin-10 (IL-10) secreted by the RS cells actively inhibit the cellular immune response.<sup>263</sup> Although EBV probably acts as an important cofactor in a multistep process leading to HD, it is likely that cellular genetic changes also play an important role since RS cells have cytogenetic abnormalities.<sup>276</sup> In fact, the EBV status of HD does not appear to impact clinical prognosis.<sup>277</sup> EBV is also found in certain forms of T-cell lymphoma.<sup>278</sup> Nasal-type angiocentric T/NK (T/natural killer)-cell lymphomas, which are prevalent in China, initially present with local involvement of the nose, skin, lung, or gastrointestinal tract, but often disseminate and run an aggressive course.<sup>279</sup> Angioimmunoblastic lymphadenopathy (AILD)-like T-cell lymphoma (Fig. 57-6) usually presents with fever, rash, dysgammaglobulinemia, hepatosplenomegaly, and lymphadenopathy.<sup>280</sup> Node-based T-immunoblastic lymphomas often have Hodgkin-like or anaplastic large cell features and in young persons may present with an infectious mononucleosis-like illness.<sup>281</sup> Some peripheral T-cell lymphomas may either develop or present with an often rapidly fatal hemophagocytic syndrome characterized by pancytopenia, a disseminated intravascular coagulation-like coagulopathy, hepatosplenomegaly, and pulmonary involvement.<sup>282</sup>

**FIGURE 57-6** Angioimmunoblastic T-cell lymphoma.

Peripheral lymphadenopathy in hemophagocytic syndrome is often unremarkable. An unusual EBV-associated syndrome described as hypersensitivity to mosquito bites has been described in Japan.<sup>283,284</sup> In these cases, EBV is found within clonal NK cells in the skin lesions as well as in blood.

## **PATHOGENESIS AND IMMUNITY**

Like the other herpesviruses, EBV may exist in either a latent or lytic state. However, the predominant mode of B-cell infection appears to lead to latency. Owing to the consistency of patterns of latent EBV gene expression seen in different cell types, these patterns have been categorized into type I typical of African Burkitt's lymphoma with *EBER1*–2 and *EBNA1* expression, type II seen in NPC and HD with *EBER1*–2 and *LMP1/2* expression, and type III seen in latent-transformed B cells with *EBER1*–2, *EBNA1*–6, and *LMP1/2* expression.<sup>285</sup> As noted previously, at least 10 latent EBV genes are active in EBV-transformed B cells, yet only a few are required for B-cell transformation.<sup>198</sup> Of the latent genes, *LMP1* is the only one that has been clearly shown to exhibit transforming function.<sup>286</sup> Although EBV-transformed B cells grow continuously in cell culture, they are normal diploid cells and unable to form tumors in nude mice and are therefore not considered malignant. African Burkitt's lymphoma cells, on the other hand, are not only EBV infected but also have a chromosomal translocation involving the *c-myc* gene on chromosome 8 and one of the immunoglobulin genes on chromosome 2 ( $\kappa$  light chain), 14 (heavy chain), or 22 ( $\lambda$  light chain). These translocations lead to production of excessive amounts of myc protein, a protein important in cell cycle progression.<sup>287,288</sup> The consistent presence of *c-myc* translocations in all cases of Burkitt's lymphoma, whether EBV positive or EBV negative, emphasizes the dominant role of the *c-myc* gene translocation in the genesis of Burkitt's lymphoma. The primacy of *c-myc* activation has also been shown in vitro by inducing proliferation of EBV-transformed B cells independent of *EBNA2* and *LMP1* activity.<sup>289</sup> However, the finding of single-sized fused EBV terminal repeats most consistent with monoclonal virus within tumors has led to the suggestion that EBV is not simply a passenger but is playing an important role in growth of the tumor.<sup>290</sup> The set of latent EBV genes (type II) active in NPC differs from that seen in transformed B cells and includes unusual complementary strand transcripts from the *Bam A* fragment.<sup>291</sup> However, advances in this area have been hampered by lack of simple in vitro systems for analysis of EBV effects on normal human epithelial cells in culture. Interestingly, the latency type II NPC pattern rather than the latency type III lymphoblastoid B-cell gene expression pattern is typical of the malignant RS cells of HD, cells which are likely B lymphoid in origin.<sup>292</sup>

## **DIAGNOSIS**

Infectious mononucleosis due to EBV may be difficult to differentiate from other infectious diseases without serologic testing for heterophile antibody and in heterophile-negative cases (in young children) for specific EBV antibody (anti-VCA). In most cases, the clinical presentation of a rapidly growing jaw or abdominal mass in a child in an endemic area is virtually diagnostic of Burkitt's lymphoma. Because of the

rapid and specific clinical presentation of endemic Burkitt's lymphoma, EBV serology has not proved useful in the diagnosis of Burkitt's lymphoma. On the other hand, the predominance of nonspecific findings (nasal stuffiness and nosebleeds) in the early stages of NPC may delay the clinical diagnosis. Fortunately, large-scale screening in susceptible populations for elevated anti-VCA or anti-EA IgA antibody titers has proved very useful in early detection of the disease and the recurrence of NPC. Recent efforts have focused on the use of BZLF1 IgG, EA IgG, and ADCC tests in prognosis.<sup>293</sup> The clinical diagnosis of post-transplant lymphoproliferative disease should be suspected if fever, lymphadenopathy, tonsillar enlargement, allograft failure, or abdominal mass is detected. Given the high rate of EBV seropositivity and viral reactivation in the transplant populations, serologic studies generally are not useful. An increase in EBV load, as assessed by quantitative EBV PCR of peripheral blood, has been shown to herald the emergence of PTLD.<sup>294–296</sup> EBV may be detected rapidly in tumor cells from tissue biopsies by immunostaining for the EBV LMP1 protein, by *in situ* hybridization for highly abundant EBV EBER-1 or EBER-2 RNA, or by detection of EBV DNA by PCR. Cell culture isolation of EBV is technically difficult and is therefore not routinely performed in the clinical laboratory.

## TREATMENT AND PROGNOSIS

Treatment of Burkitt's lymphoma and NPC with antiviral drugs is not effective—instead these malignant tumors require standard antineoplastic therapy. For NPC, radiotherapy alone often leads to 5-year survival rates of 50% to 60%.<sup>297,298</sup> Although the addition of chemotherapy leads to higher initial remission rates, no improvement in survival has been shown.<sup>299</sup> In the post-transplant setting, prophylaxis in seronegative patients with hyperimmune globulin may be useful. The nucleoside analogue acyclovir has been used in some cases to inhibit EBV replication and blunt disease, but is incapable of eradicating latent virus. In patients with severe acute complications of EBV infection, such as airway obstruction from tonsillar enlargement, corticosteroids may be useful. Appropriate treatment of PTLD should be individualized to the specific case. Options include reduction of immunosuppressive medication, interferon- $\alpha$ , intravenous immune globulin, acyclovir, localized radiotherapy, and conventional chemotherapy. Reduction of immunosuppressive therapy in the early stages of PTLD often leads to clinical remission and cure but should be carefully titrated to prevent organ transplant rejection.<sup>300</sup> Immunosuppressive withdrawal may be accompanied by acyclovir therapy, which, although ineffective in inhibiting tumor cell growth, should prevent further active viral infection. Interferon alpha-2b with intravenous immune globulin may induce remissions in both polyclonal and monoclonal PTLD and may be considered in those in whom immunosuppressive withdrawal has failed.<sup>301,302</sup> Radiotherapy should probably be limited to treatment of unresectable highly localized processes. Cytotoxic chemotherapy should probably be limited, as a last resort, to refractory cases owing to the severe life-threatening complications.<sup>303</sup> More experimental approaches with some promise include donor leukocyte transfusion and transfusion of *in vitro* expanded autologous EBV-specific cytotoxic T cells in bone marrow

transplant recipients.<sup>304,305</sup> Oral hairy leukoplakia is effectively treated with high-dose oral acyclovir or desciclovir, although recurrence following cessation of therapy is common.<sup>306,307</sup> Recent *in vitro* results suggest that vidarabine and foscarnet may be useful in treatment of EBV-positive NK large granular lymphocyte (LGL) disorders.<sup>308</sup>

## PREVENTION AND CONTROL

As with the other herpesviruses, hygienic measures are not very effective in preventing EBV infection. The large number of healthy seropositive viral excretors in the population provides a constant source of infectious virus, and measures to minimize contact with infectious saliva are impractical. Since congenital EBV infection is not a clinical problem, isolation of seronegative mothers from seropositive excretors is not warranted. Although unproven, measures to curb holoendemic malaria may be useful in prevention of Burkitt's lymphoma in central Africa, and avoidance of salted fish in southern China may be useful in prevention of NPC.<sup>231,235</sup> Ultimately, the development of an EBV vaccine may lead to decreased rates of Burkitt's lymphoma and NPC if administered to seronegative children in the endemic areas. Vaccine development has focused on the 350-kDa, major envelope glycoprotein (gp350), which is the major target of neutralizing antibodies *in vivo*.<sup>309</sup> Gp350 subunit vaccines, as well as vaccinia and adenovirus recombinant gp350 vaccines, are undergoing evaluation.<sup>310</sup>

## Human Herpesvirus 6

### AGENT

HHV-6 was first identified as a herpesvirus growing from primary lymphocyte cultures of patients with AIDS-associated lymphoproliferative disease.<sup>311</sup> The virus has subsequently been isolated from adults with AIDS<sup>312,313</sup> and children with a febrile illness called exanthem subitum (or roseola infantum, pseudorubella, or sixth disease).<sup>314</sup> The electron microscopic appearance of the virus is typical of herpesviruses with a prominent tegument.<sup>315</sup> Within 3 to 5 days of culture, infected lymphocytes display a characteristic CPE with ballooning enlargement somewhat similar to that seen with CMV.<sup>316</sup> Although the *in vitro* host cell range differs among different isolates, most can be propagated in normal T cells and T-cell lines, while some isolates have been shown to infect the fibroblast cell line MRC-5 and EBV-infected B cells.<sup>317–320</sup> *In vivo*, the major target cell in peripheral blood appears to be the CD4<sup>+</sup> CD8<sup>−</sup> T lymphocyte.<sup>321</sup> The animal host range of the virus has not been clearly established. Serologic studies in nonhuman primates have yielded mixed results, with one study detecting serologic positivity in 8 of 10 species, whereas others detected no positivity in any species tested.<sup>311,322,323</sup>

The HHV-6 genome is 160 kb to 170 kb in length with a long unique region flanked on both ends by terminal repeats.<sup>324–326</sup> Sequence analysis demonstrates that HHV-6 is a betaherpesvirus with closest homology to HHV-7 and CMV and likely encodes 80 to 100 proteins.<sup>327</sup> Genetic, serologic, and biologic evidence suggests two distinct subtypes termed HHV-6A (represented by prototype strains GS and U1102)

and HHV-6B (represented by prototype strain Z29).<sup>328,329</sup> The U1102 strain genome contains an interesting gene encoding a protein with close homology to the transregulatory rep 68/78 protein of the human parvovirus AAV-2 strain.<sup>330</sup> Transfection of NIH3T3 cells with HHV-6 DNA induces phenotypic changes associated with cell transformation, including the ability of these transfected cells to grow as tumors in nude mice.<sup>331</sup> Although a transmissible virus-like agent was demonstrated in children with exanthem subitum as early as 1950,<sup>332</sup> it was not until 1988 that HHV-6 was shown to be the cause of the disease.<sup>314</sup> It was subsequently shown that exanthem subitum is associated in almost all cases with the HHV-6B subtype.<sup>190,328,333,334</sup>

## EPIDEMIOLOGY

Like the other herpesviruses, HHV-6 is ubiquitous with greater than 80% seropositivity in U.S. adults detected with a sensitive enzyme-linked immunosorbent assay (ELISA).<sup>335</sup> Primary infection most often occurs in early childhood with seroprevalence rates exceeding 80% by 2 years of age in Japan, Italy, and Thailand.<sup>336–338</sup> HHV-6, like HHV-7, appears to persistently infect the salivary glands where it is shed into the saliva.<sup>339,340</sup> Although high rates of HHV-6 positivity in saliva from healthy adults have been reported by some researchers, others have reported much lower rates.<sup>341–346</sup> It has been suggested that the high rates of salivary HHV-6 reported in some studies may be complicated by the cross-reactivity of some reagents and assays with HHV-7.<sup>347</sup> Intrauterine infection appears to be fairly common, with nearly 30% of healthy newborns positive for HHV-6 DNA in blood. Sexual and perinatal transmission is also likely to be common given that up to 30% of uterine cervical secretions are HHV-6 DNA positive.<sup>348</sup> Primary infection in children less than 2 years old is often characterized by a syndrome of high fever and evanescent rash (exanthem subitum; Plate 57-1E). Indeed, exanthem subitum is the most common exanthem in children less than 2 years of age. Nearly half of all first febrile episodes after birth and up to 40% of all pediatric emergency room admissions for febrile illness may be due to HHV-6 infection. In one recent study, 10% of all febrile episodes in infants were due to either HHV-6A or HHV-6B infection.<sup>349</sup> In a tropical Brazilian study, primary HHV-6 and HHV-7 infections in children were often misdiagnosed as measles.<sup>350</sup>

## DISEASE

A high fever for 4 to 5 days is followed in up to 70% of cases by a diffuse evanescent (less than 2 days) maculopapular rash on the chest and abdomen with relative sparing of the face and extremities. Febrile convulsions, splenomegaly, and cervical lymphadenopathy are common. Complications may include hepatitis, thrombocytopenia, hemophagocytic syndrome, meningitis, and encephalitis. An association with a specific form of massive cervical lymphadenopathy of childhood, sinus histiocytosis with massive lymphadenopathy, has been reported.<sup>351</sup> Symptomatic primary infection in adults is neither common nor well described but may present as heterophile-negative mononucleosis or hepatitis.<sup>352,353</sup> Although HHV-6 has been suggested as a possible factor in chronic fatigue

syndrome, a prospective study was unable to establish any correlation between HHV-6 seropositivity and chronic fatigue syndrome.<sup>354</sup> HHV-6 has been implicated in some cases of idiopathic acute liver failure.<sup>355</sup> In the post-transplant setting, serologic evidence of reactivation is commonly observed and may be associated with a variety of symptoms, including fever, rash, hepatitis, pneumonitis, neurologic dysfunction, and marrow suppression.<sup>321</sup> Although HHV-6 DNA has been detected in some cases of lymphoproliferative disease,<sup>356–358</sup> the lack of consistent positivity in any specific type of lymphoproliferative disease would argue against a causal link. HHV-6 has also recently been directly implicated in the pathogenesis of multiple sclerosis.<sup>359,360</sup>

## DIAGNOSIS

Clinical diagnosis of classic roseola infantum in childhood is not usually difficult and does not require serologic confirmation. Due to the high seroprevalence, single-point IgG titers are not useful. Diagnosis of active infection serologically requires either detection of increased IgM or a greater than fourfold rise in IgG titers from paired acute and convalescent serum specimens using indirect immunofluorescence (IFA), anticomplement immunofluorescence, or ELISA. Virus culture systems have been described. However, caution in interpretation of positive results is warranted owing to the high rate of viral isolation from the normal population. Given the availability of HHV-6 DNA sequence information, the most rapid and sensitive assays for direct detection of HHV-6 are PCR-based assays, which can distinguish between HHV-6A and HHV-6B strains.<sup>333,361</sup>

## TREATMENT AND PROGNOSIS

The susceptibility of HHV-6 to antiviral drugs is likely similar to that of the related herpesvirus CMV. The nucleoside analogue, ganciclovir, and viral DNA polymerase inhibitors, cidofovir and foscarnet, may be useful in severe infection, as in the post-transplant setting, but have not been tested in a controlled manner. Although uncomplicated primary infection in childhood is self-limited, infection in immunocompromised patients such as organ transplant may lead to life-threatening complications.

## PREVENTION AND CONTROL

Given the high infection rate in infancy and childhood and the high rate of asymptomatic oral shedding, preventive measures are unlikely to be effective.

# Human Herpesvirus 7

## AGENT

HHV-7 (strain RK) was first isolated from peripheral blood CD4<sup>+</sup> T lymphocytes of a healthy 26-year-old subject during attempts to isolate and propagate HHV-6.<sup>362</sup> Several additional isolates were obtained from normal healthy persons.<sup>363</sup> Another strain (JI) was isolated from a patient with chronic fatigue syndrome.<sup>364</sup> The ultrastructural appearance of the virus is

characteristic of a typical human herpesvirus with a very prominent tegument similar to that seen with HHV-6. The HHV-7 genome is 145 kbp in size with sequence homology to other betaherpesviruses HHV-6 and CMV.<sup>365,366</sup> Antigenically, HHV-7 is similar to HHV-6 since both serologic<sup>367,368</sup> and T cell-mediated<sup>369</sup> cross-reactivity have been described. HHV-7 appears to preferentially infect CD4-positive T cells, although infection of CD8-positive lymphocytes has also been demonstrated.<sup>364</sup> Virus is present not only in peripheral blood but also in saliva, salivary glands, and uterine cervical secretions. Transmission likely occurs most commonly through the oral route, but may also occur via the genital tract.

## EPIDEMIOLOGY

HHV-7 infection is very common, with adult seroprevalence ranging from over 80% in western Europe and the United States to 60% in Japan.<sup>337,364,367,370</sup> The virus actively replicates in the oral region with salivary isolation rates of 55% to 96% of normal healthy adults.<sup>336,342,346,347,371</sup> Primary infection is common in early childhood—42% of children are seropositive by 2 years of age and 82% by 4 years of age—but appears to occur later than primary HHV-6 infection.<sup>338,372</sup>

## DISEASE

Primary HHV-7 infection in children is a febrile illness that may be complicated by seizures.<sup>373</sup> HHV-7 has been isolated from some patients with exanthem subitum, chronic fatigue syndrome, chronic mononucleosis, hepatitis, and CMV-like disease in the post-transplant setting.<sup>374–378</sup> It has been suggested both from in vitro and clinical observations that under some conditions, such as post-transplant or AIDS settings, HHV-7 may act to exacerbate other betaherpesvirus infections (CMV and HHV-6) by reactivation from latency.<sup>378,379</sup>

## DIAGNOSIS

Serologic, culture, immunohistologic, PCR, and in situ hybridization techniques for the detection of HHV-7 infection have been described but are not widely available for clinical use. However, given the high prevalence of virus infection in the normal population and the absence of clearly defined clinical disease associations, the clinical utility of viral detection or antibody titer is unclear. Assays should certainly be carefully designed and tested to avoid cross-reactivity with the related betaherpesviruses HHV-6 and CMV.

## TREATMENT AND PROGNOSIS

Although controlled studies are unavailable, it is likely that HHV-7 infection, like the betaherpesvirus CMV, will respond to treatment with the nucleoside analogue ganciclovir as well as the viral DNA polymerase inhibitors foscarnet and cidofovir.

## PREVENTION AND CONTROL

It is likely that, like HHV-6, the high infection rate in childhood and high rate of asymptomatic oral shedding in adults will preclude effective preventive measures.

# Human Herpesvirus 8

## AGENT

Infectious virus recovered from both the EBV-positive primary effusion lymphoma (PEL) cell line BC-1 and from a Kaposi's sarcoma (KS) biopsy specimen have been cloned and sequenced.<sup>380,381</sup> Although the virus was originally reported as 250 kb to 270 kb in size, a more recent estimate is 150 kb to 160 kb.<sup>382,383</sup> DNA sequence analysis has revealed close sequence homology to the gammaherpesviruses, herpesvirus saimiri and EBV.<sup>380,384</sup> A striking feature of the viral genome is the presence of genes with homology to cell cycle regulatory and signaling proteins including complement binding proteins, *bcl-2*, IL-6, IL-8 receptor, nerve cell adhesion molecule (N-CAM) family protein, macrophage inflammatory proteins (MIP-I, MIP-II), cyclin D, and interferon regulatory factor 1, some of which may be important in cell transformation.<sup>380–385</sup> No genes with homology to the known transforming genes of EBV (*EBNA*, *LMP*) or herpesvirus saimiri (*ORF1*) are present. However, it is interesting to note that EBV infection of B cells induces increased expression of some of the same cellular genes (cyclin D, complement receptor 2, *bcl-2*, IL-8 receptor-like protein, and IL-6) for which HHV-8 encodes a homologue.<sup>381</sup> This suggests that both gammaherpesviruses use the same strategy for successful infection, but in the case of EBV the elements of the program remain within the human host cell while with HHV-8 the program has been acquired by the virus from the host cell.

## EPIDEMIOLOGY

PEL cell lines have been utilized as targets for the development of IFA and ELISA assays for detection of anti-HHV-8 antibodies in human serum. Assay variations have included IFA on unstimulated cells, phorbol ester or *N*-butyric acid-stimulated cells for more sensitive detection of antibody to lytic antigens,<sup>386–389</sup> isolated cell nuclei for detection of antibody to nuclear antigens,<sup>386,390,391</sup> and ELISA using recombinant antigens.<sup>391</sup> As expected, nearly all patients with KS are seropositive using any of the preceding methods. Also, not surprisingly, a variable proportion of AIDS patients without KS are seropositive. Both seroconversion and detection of HHV-8 DNA by PCR were shown to precede development of KS in HIV-positive patients.<sup>390,392,393</sup>

Immunosuppressed renal transplant recipients exhibit both serologic and molecular evidence of HHV-8 activation,<sup>394</sup> a phenomenon that may be at least partially due to steroid effects on viral replication.<sup>395</sup> Transmission of HHV-8 in transplant recipients may occur by blood transfusion or by allograft transmission.<sup>396,397</sup> Tremendous geographic variation in HHV-8 seroprevalence has been noted. In central Africa, the seroprevalence is approximately 50%, while in southern Europe it ranges up to 20% and is about 5% in northern Europe and in the United States.<sup>398</sup> Seroprevalence rates reported from different laboratories on normal healthy controls from nonendemic regions have varied tremendously (0 to 24%).<sup>387–391</sup>

Although some variations in results may be due to real geographic or demographic differences, some variability is also likely due to differences in the sensitivity of assay signal detection and the selection of antigen substrate.<sup>399</sup> Seroprevalence studies

designed to detect the age of infection have revealed that as contrasted with an early age of infection in Africa,<sup>400</sup> in the United States infection appears to be delayed until adolescence.<sup>401</sup>

## DISEASE

The clinical characteristics of primary HHV-8 infection have not yet been described. In addition to KS, HHV-8 has also been detected by PCR in high-grade large B-cell lymphomas arising in body cavities, that is, primary effusion lymphoma,<sup>402–404</sup> multicentric Castlemans disease,<sup>405</sup> AILD,<sup>406</sup> non-KS skin tumors in allograft transplant recipients,<sup>407</sup> angiosarcoma,<sup>408</sup> and multiple myeloma.<sup>409</sup>

KS was first described by Kaposi as an indolent tumor of the lower extremity in elderly males of Mediterranean or eastern European descent.<sup>410</sup> KS is a dermal spindle cell neoplasm, likely of endothelial cell origin, which in the skin is manifest as irregular discolored patches, plaques, nodules, or umbilicated tumors (Plate 57-1F). Although most investigators regard KS as a malignant disease, the indolent behavior of classic KS with spontaneous regression seen in some cases has led some to suggest a reactive process.<sup>411,412</sup> Analysis of DNA of KS lesions has yielded inconsistent results, with some studies suggestive of a nonclonal process and other studies suggestive of a clonal process.<sup>413,414</sup> Pathologically, the early lesion (the patch stage) consists of irregular branching ectatic vascular channels in the upper dermis lined by plump relatively normal-appearing endothelium (Fig. 57-7). At this stage, the pathologic changes may be subtle, and distinction from hemangioma or granulation tissue difficult. The late lesion (the plaque stage) consists of an irregular nodular spindle cell proliferation with mitotic figures in both the upper and lower dermis, vascular slits, extravasated erythrocytes, hemosiderin deposition, so-called hyaline bodies, and admixed inflammatory cells. At this stage, the pathologic changes are quite characteristic, although in some cases distinction from angiosarcoma may be difficult. KS has been described in four different clinical settings—classic Mediterranean, endemic African, epidemic AIDS associated, and iatrogenic.<sup>415</sup> Classic KS presents as a chronic, generally indolent, cutaneous disease of the lower extremity, most often in elderly white males (male-to-female ratio, 3:1; mean age, 68 years) of Mediterranean, eastern

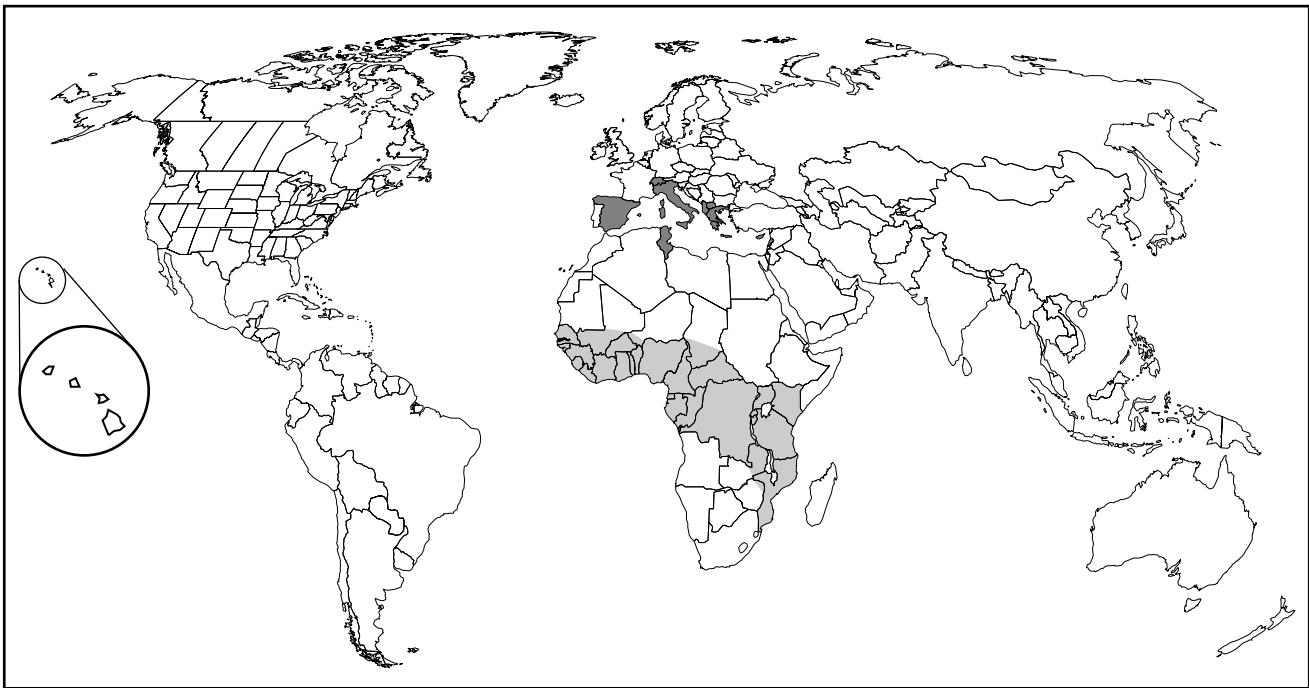

European, or Jewish ancestry.<sup>410</sup> Interestingly, up to 35% of these persons may develop second tumors, especially malignant lymphoma. Endemic African KS occurs in the sub-Saharan equatorial regions and presents most often in young adult black males (male-to-female ratio, 14:1; mean age, 35 years) with either a florid form (40%), a benign nodular form (25%), or an aggressive form (15%), as well as in young black male children (mean age, 3 years) with a lymphadenopathic form.<sup>416</sup> Endemic KS is often an aggressive disease with a fatal outcome. Iatrogenic KS occurs in persons following chronic treatment with drugs with immunosuppressive effects administered for solid organ transplantation,<sup>246,417</sup> autoimmune disease,<sup>418</sup> and malignancy. Iatrogenic KS is a generally indolent disease with complete remission in up to 24% of cases following immune restoration. Epidemic AIDS-associated KS is the most common malignant neoplasm in AIDS patients in the Western world.<sup>419</sup> The risk of development of KS in AIDS appears to be directly related to the degree of immunodeficiency and is strongly inversely correlated with the absolute CD4 count. Sexual transmission of HHV-8 is suggested by the much higher incidence of KS in HIV-positive homosexual or bisexual males than in other risk groups such as HIV-positive females and IV drug users. AIDS-associated KS is an aggressive disease closely resembling endemic African KS, with widespread dissemination to lymph nodes and viscera.

Although HHV-8 is nearly always detected in KS lesions within the KS spindle cells, the role HHV-8 plays in the pathogenesis of KS is unclear. Prior to the discovery of HHV-8, work was presented implicating CMV as the causative agent of KS.<sup>420–422</sup> Also, inflammatory cytokines (basic fibroblast growth factor, oncostatin M, and IL-6) from activated T cells and the HIV-1 tat protein have been shown to induce KS-like spindle cell transformation of normal endothelium both in vitro and in vivo.<sup>423–429</sup> Results of DNA analysis of KS spindle cells are not consistent, with some reporting diploidy and others aneuploidy.<sup>429–432</sup> Although no consistent KS-specific chromosomal abnormality has been described, chromosome X inactivation analysis reveals that AIDS KS is a monoclonal tumor.<sup>433</sup> Analysis of HHV-8 terminal repeats by Southern blotting in a KS biopsy are consistent with monoclonal virus, a finding most consistent with tumor cell monoclonality, as would be expected if KS were a malignant neoplasm.<sup>380</sup> Despite these findings, the absence of HHV-8 in spindle cell cultures derived from KS biopsies is puzzling.<sup>434,435</sup> Perhaps HHV-8 is lost from cells after serial passage in vitro.

Castleman's disease is a peculiar lymphoproliferative disorder which presents either as a solitary or multicentric form.<sup>436,437</sup> The more common solitary form usually presents asymptotically as an anterior mediastinal or neck mass with hyaline vascular histology. The less common multicentric form usually presents with fever, anemia, and generalized lymphadenopathy with plasma cell histology. Patients with the solitary form have an excellent prognosis and in fact are often cured of disease by surgical excision of the mass. On the other hand, patients with the multicentric form have a poor prognosis. Lymph node biopsies of multicentric Castleman's disease may contain HHV-8 DNA by PCR.<sup>405</sup> However, the significance of these findings is unclear since only a minority of cases contain viral DNA.<sup>438</sup> Regarding non-KS vascular lesions, in one PCR study of 155 vascular lesions (including 17 cases of KS and 15 cases of angiosarcoma), HHV-8 DNA

**FIGURE 57-7** Kaposi's sarcoma. (Courtesy of Joanna Borkowski, MD, Department of Pathology, UTMB, Galveston, TX.)

### Kaposi's Sarcoma

- Classic Mediterranean Kaposi's Sarcoma
- Endemic African Kaposi's Sarcoma

was present only in the KS cases, while in another study HHV-8 was found in angiosarcoma (7 of 24) and hemangioma (1 of 20).<sup>408,439</sup> The significance of these findings is unclear since only a minority of cases contain viral DNA.

PEL is a high-grade malignant lymphoma most often seen in homosexual males with AIDS.<sup>255,403,404,440,441</sup> The tumor presents as a malignant effusion of pleural, pericardial, or peritoneal cavities and tends not to disseminate but to remain confined to the body cavity. Despite the lack of dissemination, these patients do not tolerate chemotherapy well and succumb within a few months of diagnosis. The malignancy is composed of large anaplastic cells with a null cell immunophenotype (negative B- and T-cell markers, CD30-positive) and a B-cell genotype (Jh rearranged) and are usually coinfecting with both EBV and HHV-8.<sup>401</sup> Interestingly, up to one third of PEL cases may be associated with KS.<sup>442</sup> Although usually seen in males with AIDS, rare HHV-8-positive PELs have been described in HIV-negative males and females.<sup>404,442,443</sup>

Multiple myeloma, a malignant plasma cell neoplasm which arises in the bone marrow, is the second most common malignancy of the blood in the United States.<sup>444</sup> Monoclonal gammopathy of undetermined significance (MGUS) is an even more common related condition characterized by a monoclonal proliferation of plasma cells but accompanied by much less severe clinical findings. However, up to 25% of patients with MGUS progress to multiple myeloma.<sup>445</sup> Although HHV-8 DNA had previously been shown to be absent from myeloma cells, HHV-8 DNA was recently reported within the dendritic cell compartment of the bone marrow of 15 of 15 patients with myeloma and two of eight patients with MGUS, while absent from 10 normal bone marrow samples

and 16 samples from patients with other malignancies.<sup>409,446</sup> The authors suggest that the role of the infected dendritic cells may be in stimulating growth of the abnormal plasma cells by elaboration of HHV-8 vIL-6, a factor shown to support the growth of a murine plasmacytoma cell line.<sup>382</sup>

### PATHOGENESIS AND IMMUNITY

HHV-8 was first detected as a unique DNA sequence from an AIDS KS skin biopsy using PCR-based representational difference analysis.<sup>447</sup> Subsequently, this DNA sequence was detected by PCR in nearly all lesional skin biopsies from patients with all forms of KS—classic, endemic African, iatrogenic, and epidemic AIDS associated.<sup>447–451</sup> Virus has been localized within the KS tumor cells by in situ hybridization.<sup>452,453</sup> However, viral DNA has also been detected in other tissues as well, including nonlesional skin,<sup>385</sup> non-KS skin tumors,<sup>407</sup> peripheral blood,<sup>454</sup> lymphoid tissue,<sup>455</sup> saliva,<sup>456–458</sup> sensory ganglia,<sup>459</sup> semen,<sup>460,461</sup> and prostate tissue. However, some of these findings have been disputed by others.<sup>451,462,463</sup> HHV-8 DNA has been found not only in KS patients but also in human immunodeficiency virus (HIV)-positive persons without KS as well as HIV-negative healthy controls. Within the blood, the virus has been localized largely to the CD19 B-cell compartment, although it may also be found in some T cells.<sup>464</sup> HHV-8 DNA has also been detected in some cases of AIDS-associated primary effusion B-cell lymphoma (PEL) where it may be accompanied by EBV.<sup>402,438,465</sup> Infectious virus obtained from the PEL cell line BC-1 has been shown in vitro to infect normal peripheral blood B cells.<sup>466</sup> HHV-8 DNA has been detected in biopsy material from non-KS skin lesions (squamous cell carcinoma,

basal cell carcinoma, actinic keratosis, Bowen's disease) and also from normal skin of HIV-negative persons.<sup>467</sup> HHV-8 has also been found in some cases of AIDS-associated multicentric Castleman's disease.<sup>405</sup> In another study, HHV-8 DNA was detected by PCR only occasionally in biopsy material from patients with HIV-negative reactive lymphadenopathy (4 of 23 patients), HIV-negative angioimmunoblastic lymphadenopathy (3 of 15), lymphoma (1 of 43), multicentric Castleman's disease (0 of 5), and Hodgkin's disease (0 of 45).<sup>406</sup> The HHV-8-positive reactive lymphadenopathy changes were characterized by florid follicular hyperplasia with increased vascularity resembling HIV-related lymphadenopathy and multicentric Castleman's disease. Normal healthy controls have also been shown to harbor HHV-8 DNA albeit at a lower rate.<sup>406,461</sup> In one study, HHV-8 DNA was found in 6% of normal skin tissues, in 7% of peripheral blood samples, in 44% of prostate tissues, and in 91% of semen samples from healthy immunocompetent Italian males.<sup>468</sup> It has been reported that not only HHV-8 but also EBV and CMV may be detected in African KS biopsies, and CMV, HHV-6, HHV-7, and human papillomavirus in AIDS KS biopsies.<sup>469–471</sup> However, the lack of consistent positive results in these studies argues against these other viruses playing an etiologic role. The increasing number of reports of HHV-8 PCR positivity in normal and abnormal tissues from patients without KS strongly suggests that viral infection may not be strictly limited to persons with KS. It is possible that HHV-8, like the related gammaherpesvirus EBV, will prove to be present not only in patients with virus-associated neoplasms but also in normal persons and serve as an important cofactor in human tumorigenesis, especially in a setting of immunodeficiency.

Coculture of KS spindle cells with a variety of endothelial and epithelial cell lines led to lytic infection of approximately 1% of the cells of the embryonal kidney epithelial cell line 293 from which virus could be serially passaged.<sup>472</sup> Interestingly, virus obtained from an HHV-8-positive, body cavity-based lymphoma cell line did not induce any evidence of infection. Infection of primary microvascular endothelial cells by HHV-8 has been reported and in two cases was associated with cellular transformation.<sup>473–475</sup> Like all herpesviruses, the virus appears to reside within infected cells either in the latent state as a circular episomal form or in the lytic state as a linear form. In one report, it was shown that linear lytic virus is found in the peripheral blood, whereas only episomal latent virus is present within the KS skin lesion itself.<sup>454</sup>

## DIAGNOSIS

Because of the very strong correlation of HHV-8 positivity with KS, diagnosis of KS is presumptive evidence of HHV-8 infection. Rapid and specific confirmation of HHV-8 infection, however, may be accomplished by both qualitative and quantitative PCR methods performed on DNA isolated from body fluids or tissue.<sup>447,476</sup> Serologic assays (IFA nuclear antigen assay, IFA lytic antigen assay, ELISA recombinant antigen assay) are currently under development and will likely prove very useful in seroprevalence studies, in characterization of the immune response, and in detection of primary infection (IgM-specific assays). Although an *in vitro* culture method has recently been described, the technical complexity of the

method in its current form makes it unlikely to be useful in the clinical laboratory setting.<sup>472</sup>

## TREATMENT AND PROGNOSIS

Although HHV-8 infection may not respond to treatment with the nucleoside analogues acyclovir and ganciclovir as well as the other herpesviruses, long-term remission of KS has been reported following treatment with foscarnet,<sup>477</sup> and HIV-positive patients treated with foscarnet or ganciclovir have a decreased risk of KS development.<sup>478</sup> Also, clearance of HHV-8 DNA from the peripheral blood of an HIV-positive patient following treatment with the HIV protease inhibitor indinavir has been reported.<sup>479</sup> The use of highly active antiretroviral therapy (HAART) in AIDS-related KS is associated with a dramatic clinical response. Local therapy of KS has included cryotherapy, surgical excision, intralesional vinblastine, vincristine, or interferon- $\alpha$ , and radiotherapy. Systemic therapy has included both single- and multiple-agent chemotherapy and interferon- $\alpha$ .<sup>480</sup> Anti-neoplastic agents such as liposomal anthracyclines and paclitaxel, as well as antiangiogenic agents such as retinoic acids, AGM 1470 (TNP 470), thalidomide, and glufanide disodium (IM 862) have shown some promise in patients with KS.<sup>481</sup>

## PREVENTION AND CONTROL

At this time there is no specific information regarding methods of prevention or control of HHV-8 infection. However, the best prevention advice is to reinforce the more general safe sex practices that have been promoted to prevent human immunodeficiency virus and other sexually transmitted diseases.

## ■ Cercopithecine Herpesvirus 1

### AGENT

CHV-1, or B virus, is a simian herpesvirus indigenous to Asian monkeys of the genus *Macaca*, including rhesus and cynomolgus species. The virus was first isolated from the first reported human case in a laboratory worker in 1932,<sup>482,483</sup> and it was not until 1954 that the virus was isolated from the spinal cord of a rhesus monkey that was being used in poliovirus research.<sup>484</sup> Nucleotide sequence analysis indicates that of the human herpesviruses HSV-1 is most similar to CHV-1.<sup>485,486</sup> The genome is larger than that of HSV-1 and is composed of a long and short unique region, each flanked by inverted repeat sequences like that of HSV-1. The complete 157-kbp nucleotide sequence of strain E2490 was recently completed.<sup>487</sup> Unexpectedly, the virus apparently lacks a homolog of the HSV-1 34.5 gene encoding a neurovirulence factor. Serologic cross-reactivity between CHV-1 and HSV-1 often leads to serious difficulties in the interpretation of assay results.

### EPIDEMIOLOGY

CHV-1 is the only nonhuman primate herpesvirus that has been shown to infect humans. Monkeys of the genus

*Macaca*, including rhesus and cynomolgus species native to Asia and northern Africa, have adult seroprevalence rates of greater than 80%.<sup>488</sup> However, only 2% to 3% of seropositive monkeys shed virus at any particular time.<sup>489</sup> Although no other Old World or New World monkeys are known to naturally harbor virus, the virus can induce fatal disease in non-macaque primates, including man. Clinically apparent infection in housed monkeys is usually manifest as a self-limited oropharyngeal and mucocutaneous infection that resembles human HSV-1 infection. However, cases of disseminated infection with interstitial pneumonitis, hepatitis, gastrointestinal involvement, and a high mortality rate have been reported. A prospective 16-month study of 157 housed rhesus monkeys detected nine symptomatic infections—eight recurrent and one primary infection.<sup>490</sup> The risk of infection increased with age, and transmission occurred only during the breeding season. Virus could be isolated from both oral and genital tissues. Like HSV in man, CHV-1 remains latent within sensory ganglia of monkeys following primary infection.<sup>489</sup>

## DISEASE

Human infection with CHV-1 is rare—fewer than 40 cases have been described.<sup>491</sup> A serologic study of 321 primate handlers revealed no cases of asymptomatic infection.<sup>492</sup> Humans are infected in most cases by animal bite, but transmission has also occurred following direct inoculation of the eye or respiratory tract with monkey body fluids. Person-to-person transmission from intimate contact with vesicular lesions has been documented in a single case in Florida. In most cases, after an incubation period of 3 to 5 days, a localized vesicular eruption at the site of inoculation is accompanied by fever, myalgia, headache, or nausea. The vesicular eruption is clinically and pathologically similar to that caused by HSV. Neurologic symptoms follow 3 to 7 days after development of the vesicular eruption. Paresthesia or hyperesthesia of the affected limb is followed rapidly by weakness and paralysis. Transverse myelitis may be followed by signs of encephalitis and neurologic death. At least one case has been described without bite or scratch wounds and with only nonspecific symptoms followed 5 days later by neurologic symptoms. Although uncommon, respiratory transmission followed by fever, pneumonitis, and neurologic symptoms has also been reported.

## DIAGNOSIS

The clinical diagnosis of CHV-1 infection in man should be suspected in persons with fever, myalgia, and neurologic complaints in close contact with monkeys of the *Macaca* genus, particularly in confined animals with HSV-1-like vesicular oropharyngeal lesions. CHV-1 infection should be differentiated from the much more common HSV-1 infection. The vesicular eruption of HSV infection is virtually indistinguishable both clinically and pathologically from CHV-1 infection. However, given the clinical settings in which humans come into contact with CHV-1, this distinction should in most cases not be difficult. Although the high degree of antigenic cross-reactivity of HSV and CHV-1 make serologic distinction difficult,<sup>493</sup> serologic tests which apparently do not cross-react with HSV have been

recently described.<sup>492,494,495</sup> Specific diagnosis can also be made by viral culture<sup>492</sup> or PCR.<sup>496,497</sup>

## TREATMENT AND PROGNOSIS

All bites or scratches should be immediately cleaned vigorously with soap or detergent, and eyes and mucous membranes should be vigorously rinsed with sterile saline. The cleaning and rinsing procedures are followed immediately by collection of a swab of the wound or scratch for culture and a serum sample for baseline “acute” serology. Serum is collected again after 3 weeks for “convalescent” serology. Following risk assessment, postexposure prophylaxis with a 14-day course of oral valacyclovir or acyclovir is recommended. For B virus disease, treatment with intravenous acyclovir or ganciclovir is recommended until all symptoms resolve and two consecutive virus cultures are reported negative.<sup>498</sup> Immune globulin has not been shown to be efficacious.<sup>499</sup> The monkey should be isolated, examined, and treated, if appropriate, by a veterinarian. Human infection often leads to a rapidly ascending encephalomyelitis with historical overall mortality rate of 70%—a rate similar to untreated HSV encephalitis.<sup>500</sup> However, more recently the case-fatality rate has declined, probably owing to more rapid therapeutic intervention.

## PREVENTION AND CONTROL

CHV-1 infection in humans will most effectively be prevented by establishment of virus-free colonies of macaques. Certainly, all persons who are in contact with Asian macaque monkeys should be trained to recognize the herpes simplex–like mucocutaneous lesions characteristic of infection in monkeys. These animals should be isolated and treated accordingly. A meeting cosponsored by the Centers for Disease Control and Prevention (CDC) and Emory University in Atlanta first put forth recommendations regarding prevention and treatment of CHV-1 infections in 1995.<sup>501</sup> These recommendations were recently updated in 2002.<sup>498</sup> All macaques should be presumed to be infectious at all times and handled accordingly.

## ACKNOWLEDGMENTS

Our sincere appreciation to Ruthie Williams and Linda Beachey of the University of Texas Medical Branch (UTMB) Hematopathology Division for their secretarial assistance, and to Dr. Stephen Tying of the UTMB Departments of Dermatology and Microbiology and Immunology for his expert information regarding antiviral therapy and dermatologic manifestations of herpesvirus infections.

# Smallpox and Monkeypox

DONALD A. HENDERSON  
LUCIANA L. BORIO

## INTRODUCTION

Smallpox, although now eradicated, poses a potential threat to all countries should strains of the virus be accidentally released or deliberately disseminated as an act of biological terrorism. Smallpox was once by far the most serious of all infectious diseases, killing 25% to 30% of unvaccinated persons who became infected.<sup>1</sup> Under the aegis of the World Health Organization (WHO), eradication was achieved during a 10-year program culminating in the occurrence of the last case on October 26, 1977.<sup>1</sup> In 1980, vaccination was stopped in all countries except for workers in *Orthopoxvirus* research laboratories and some military services. Two laboratories, one in the United States and one in Russia, have been authorized officially by the World Health Assembly to retain stocks of the virus. However, other stocks may be present in Russia or other countries at unpublicized sites. Should the virus be released, either deliberately or accidentally, a global calamity could result because population immunity is now very low, reserve supplies of vaccine are limited, and only a few producers have a capacity to manufacture more. For these reasons, the occurrence of a suspected case of smallpox, wherever found, is a public health emergency, warranting immediate and thorough investigation by national and international authorities.

Monkeypox, the only other member of the *Orthopoxvirus* genus to cause serious systemic human infection, induces an illness that may be all but indistinguishable clinically from smallpox but is associated with a lower person-to-person transmission rate and has case-fatality rates of 10% to 15%.<sup>2</sup> First detected in 1970 in the Democratic Republic of the Congo (renamed Zaire between 1971 and 1997), cases subsequently have been found scattered across tropical rain forest areas of Africa extending from Congo to the Ivory Coast. Most cases, however, have been found in Congo. In contradistinction to smallpox, monkeypox has a zoonotic reservoir, including African ground squirrels and perhaps other rodents, and in the past has spread infrequently from person to person. In 1996 to 1997, however, outbreaks of more than 300 cases of monkeypox were reported from one area in Congo with epidemiologic characteristics suggesting the possibility that monkeypox might be able to spread more widely in a now largely unvaccinated population.<sup>3</sup> The fact, however, that major outbreaks of varicella were occurring concomitantly

(M. Szczeniowski, personal communication, 1998) has confused the epidemiologic picture. Special studies are continuing.

In the summer of 2003, an outbreak of monkeypox affected 72 persons in the midwestern United States who had contact with infected prairie dogs from a single distributor. This was the first outbreak of monkeypox in the Western Hemisphere. In this outbreak, no cases of monkeypox could be attributed exclusively to person-to-person transmission. This outbreak led the Centers for Disease Control and Prevention (CDC) and the Food and Drug Administration (FDA) to ban the importation, sale, distribution, transport, and release into the environment of prairie dogs and several other African rodent species.<sup>4</sup>

## AGENTS

### History of Smallpox

Because smallpox has no animal reservoir and no human carrier state, it is assumed to have emerged from an animal reservoir sometime after the first agricultural settlements, about 10,000 BC,<sup>5</sup> when populations were large enough to sustain human-to-human transmission of the virus. The first certain evidence of smallpox in the ancient world comes from mummified remains of the Eighteenth Egyptian Dynasty (1580–1350 BC) and of the better known Ramses V (1157 BC).<sup>6</sup> Written descriptions of the disease, however, did not appear until the fourth century AD in China<sup>7</sup> and the tenth century in southwestern Asia.<sup>8</sup>

From northeastern Africa, smallpox was probably carried by Egyptian traders to India during the first millennium BC,<sup>1</sup> where it became established as an endemic infection. Although epidemics of disease are described in the Bible and in Greek and Roman literature, descriptions of clinical signs are sparse and there is no original Greek or Latin word for smallpox despite its distinctive rash.<sup>9</sup> From the populated endemic areas of Asia and perhaps Africa, smallpox spread with increasing frequency into less populous areas of these continents and into Europe, becoming established as an endemic infection when populations increased sufficiently in number.

The name “variola” was first used during the sixth century by Bishop Marius of Avenches (Switzerland), the word being derived from the Latin *varius* (“spotted”) or *varus* (“pimple”).<sup>10</sup> There is little doubt that smallpox was already endemic in some areas of Europe by this time.<sup>7</sup> In the Anglo-Saxon world of the tenth century, the word *poc* or *pocca*, a bag or pouch, described an exanthematous disease, possibly smallpox, and English accounts began to use the word *pockes*. With the appearance of syphilis in Europe in the late fifteenth century, writers began to use the prefix *small-* to distinguish variola, the smallpox, from syphilis, the great pox.<sup>11</sup>

In the early sixteenth century, smallpox began to be imported into the Western Hemisphere. Catastrophic epidemics followed, which decimated Amerindian tribes and resulted in the collapse of both the Aztec and Incan empires.<sup>5</sup> Central and southern Africa probably became endemic for smallpox about this time or soon thereafter.

The impact of smallpox on history and human affairs was profound.<sup>7</sup> Deities to smallpox became a part of the cultures of India, China, and parts of Africa. In Europe, as of the end of the eighteenth century, an estimated 400,000 persons died

annually from smallpox, and survivors accounted for one-third of all cases of blindness. During the eighteenth century alone, five reigning European monarchs died of smallpox, and the Austrian Hapsburg line of succession shifted four times in four generations.

A method of protection against naturally acquired smallpox infection appears to have been discovered in India sometime before AD 1000.<sup>12,13</sup> There it became the practice to deliberately inoculate, either into the skin or by nasal insufflation, scabs or pustular material from lesions of patients. This practice resulted in an infection that was usually less severe than an infection acquired naturally. From India, the practice spread to China, western Asia, and Africa, and finally, in the early eighteenth century, to Europe and North America.<sup>14</sup> Case-fatality rates associated with variolation, as it was called, were about one-tenth as great as when infection was naturally acquired, but those infected in this manner were capable of transmitting smallpox to others. After cowpox began to be used as a protective vaccine, the practice of variolation diminished. Even as recently as the 1960s and 1970s, however, variolation continued to be performed among remote populations in some parts of Ethiopia, western Africa, Afghanistan, and Pakistan.<sup>1</sup> In 1796, Edward Jenner demonstrated that material could be taken from a human pustular lesion caused by cowpox virus (i.e., an *Orthopoxvirus* species closely related to smallpox virus) and inoculated into the skin of another person, producing a superficial infection with few symptoms.<sup>15</sup> He showed that the individual, after recovery, was protected from inoculation with smallpox. He called the material *vaccine*, from the Latin *vacca* ("cow"), and the process *vaccination*. Pasteur,<sup>16</sup> in recognition of Jenner's discovery, later broadened the term to denote preventive inoculation with other agents. Jenner's discovery was immediately recognized for its significance. Within 5 years, his paper had been translated into six languages,<sup>17</sup> and the vaccine had begun to be employed widely in many countries of Europe; within a decade, it had been transported to countries throughout the world.<sup>18</sup>

As the nineteenth century progressed, however, the initial wave of enthusiasm for vaccination subsided as difficulties were experienced in sustaining the virus through arm-to-arm inoculation and it was found that, on some occasions, syphilis was transmitted in the process.<sup>19,20</sup> Although vaccination material, dried on threads or ivory points, could be transported over long distances, it was often found, on receipt, to be non-infectious. When fresh material was sought, problems occurred because the cowpox disease was found only in Europe and was only sporadically present.<sup>21</sup> In some areas, significant opposition to vaccination was voiced by religious leaders and anti-vaccinationist societies who opposed, on principle, infecting humans with an animal disease.<sup>22</sup>

Growth of the virus on the flank of a calf offered the prospect for provision of an adequate and safer supply of vaccine material. Although this approach was employed in Italy as early as 1805,<sup>23</sup> it appears to have been largely unknown elsewhere until it was more widely publicized at a medical congress in 1864.<sup>24</sup> Thereafter, the practice was gradually adopted in other countries, although arm-to-arm vaccination in England, for example, continued until it was finally banned in 1898.<sup>25</sup> With an assured source of vaccine, the numbers of vaccinations increased, and the incidence of smallpox in the more

industrialized countries diminished rapidly. However, not until after World War I did most of Europe become smallpox-free, and not until after World War II was transmission stopped throughout Europe and North America.

In most other parts of the world, especially in tropical and semitropical areas and in the developing countries, smallpox continued largely unabated until the middle of the twentieth century. In these countries, continuing difficulties were experienced in sustaining the virus through arm-to-arm inoculation. After calves began to be used for vaccine production, the harvested vaccine remained viable for only 1 or 2 days at ambient temperatures, thus limiting its widespread application. The only control programs that were notably successful were those in Indonesia and in certain of the French colonies, which, in the 1920s, began using a specially prepared and more stable air-dried<sup>26</sup> or freeze-dried<sup>27</sup> vaccine.

In the late 1940s, a commercially feasible process for large-scale production of a highly heat-stable freeze-dried vaccine was perfected.<sup>28</sup> This process offered vastly better possibilities for smallpox control. Recognizing the value of such a vaccine, the Pan American Sanitary Organization<sup>29</sup> decided, in 1950, to undertake a hemisphere-wide eradication program and by 1967 succeeded in eliminating smallpox from all countries of the Americas except Brazil. Meanwhile, in 1958, the U.S.S.R. proposed to the World Health Assembly that a global smallpox eradication program be undertaken,<sup>30</sup> and this was so decided the following year.<sup>31</sup> Some progress was made during the period from 1959 to 1966, but the results overall were disappointing. Finally, in 1966, the World Health Assembly decided to intensify the eradication program by providing additional funds specifically for this effort.<sup>32</sup>

During 1967, the year the Intensified Global Eradication Program began, an estimated 10 to 15 million smallpox cases<sup>33</sup> occurred in 31 countries in which the disease was endemic. The campaign was based on a twofold strategy: (1) mass vaccination campaigns that would reach at least 80% of the population using vaccine of assured potency and stability and that would be assessed by independent teams, and (2) development of a system to detect and contain cases and outbreaks.<sup>34</sup> Numerous problems had to be surmounted, including deficient supervision and discipline in national health services, epidemic smallpox among refugees fleeing areas stricken by civil war and famine, shortages of funds and vaccine, and a host of other problems posed by difficult terrain, climate, and cultural beliefs.<sup>35–37</sup> Despite the problems, steady progress was made, and on October 26, 1977, the last known naturally occurring case of smallpox was recorded in Merka, Somalia.<sup>38</sup> Two further cases occurred in 1978 as a result of a laboratory infection in Birmingham, England,<sup>39</sup> but these cases were the last. Detailed accounts of national programs are provided in books dealing with those in India,<sup>40,41</sup> Bangladesh,<sup>42</sup> Ethiopia,<sup>43</sup> and Somalia.<sup>44</sup>

An extensively illustrated volume entitled *Smallpox and Its Eradication*<sup>1</sup> provides a detailed account of the eradication campaign, as well as an overall account of progress in smallpox control through history. It also gives a description of the virology, the clinical features, and the pathogenesis of the disease. Complementing this text is a historical record of smallpox, *The Greatest Killer: Smallpox in History*, by Donald R. Hopkins.<sup>7</sup>

## History of Monkeypox

Monkeypox was first described in 1959 as a primate infection in a Danish laboratory<sup>45</sup> and subsequently was determined to be the cause of eight additional laboratory outbreaks between 1958 and 1968.<sup>46</sup> In August 1970, the first human case was identified in a tropical rain forest village in Equateur province, Democratic Republic of the Congo.<sup>47</sup> Clinically, the disease closely resembles smallpox. Most patients, however, exhibit cervical, axillary, and sometimes inguinal lymphadenopathy, which are almost never observed with smallpox. It is assumed that the disease was prevalent for many years, not being identified as such until smallpox transmission was interrupted throughout the rain forest areas and surveillance for smallpox-like diseases was greatly enhanced.

Between 1970 and 1995, more than 400 human cases of monkeypox were detected, mainly in Zaire. The cases were scattered, primarily occurring as single cases in a village, but in some few instances it was clear that human-to-human transmission could occur. Investigations revealed that the virus had a natural reservoir in ground squirrels and possibly other rodents, man and monkeys being only incidental hosts. An outbreak in 1996 to 1997 of more than 300 possible cases of monkeypox in central Zaire raised the question at first as to whether human-to-human transfer of virus might occur more frequently than had been thought<sup>3</sup> (Fig. 58-1). However, a simultaneous outbreak of varicella was found to be occurring in the same region, and it was clear that a substantial number of the suspected monkeypox cases were actually varicella cases.<sup>48</sup> In the U.S. outbreak of 2003, most patients with monkeypox reported exposure to wild or exotic mammals (including prairie dogs), and some patients were also household contacts of affected people. However, no cases of monkeypox could be attributed exclusively to person-to-person contact.<sup>49</sup>

## Taxonomy

Variola and monkeypox viruses belong to the genus *Orthopoxvirus*, subfamily Chordopoxvirinae, family Poxviridae. Two other members of this genus, vaccinia and cowpox, also can infect humans, causing cutaneous lesions, but those viruses are seldom transmitted from person to person. The poxviruses are the largest and most complex of all viruses. The virion is a brick-shaped structure with a diameter of about 200 nm.<sup>50</sup> An outer membrane of tubular lipoprotein subunits, arranged irregularly, encloses a dumbbell-shaped core and two “lateral bodies” of unknown nature. The core contains the viral DNA and associated proteins. There is an envelope that contains cellular lipids and several virus-specific polypeptides.

Restriction endonuclease maps of the genome definitively identify the species of the *Orthopoxvirus* genus. Smallpox and monkeypox are most closely related and have more than 95% homology. There are more than 100 polypeptides in the virion. The core proteins include a transcriptase, several other enzymes, and numerous antigens recognizable by immunodiffusion. The lipoprotein outer membrane of the virion is synthesized de novo; the envelope, when present, is derived from membranes of the Golgi apparatus but contains several virus-specific polypeptides. Most proteins are common to all members of the genus, and there is extensive cross-protection and cross-neutralization among them.

**FIGURE 58-1** Congolese boy showing the typical rash of monkeypox. Although the causal virus is different from smallpox virus, the rash is indistinguishable from clinical smallpox. (Courtesy of the World Health Organization, Geneva.)

## Cell Cycle

A specific cell-surface receptor for smallpox virus has not been identified.<sup>51</sup> Once inside the cell, replication of the poxviruses occurs in the host cell's cytoplasm.<sup>50</sup> Unlike other DNA viruses, the poxviruses encode the dozens of enzymes required for transcription and replication of the viral genome. The viral core is released into the cytoplasm after fusion of the virion with the plasma membrane. Transcription is initiated by the viral transcriptase. A transcription factor, capping and methylating enzymes, and a poly (A) polymerase enable functional capped and polyadenylated messenger RNAs (mRNAs) to be produced, without splicing, within minutes after infection. The polypeptides produced by translation of these mRNAs complete the uncoating of the core. Transcription of about 100 genes, distributed throughout the genome, occurs before viral DNA synthesis begins. Early proteins include DNA polymerase, thymidine kinase, and other enzymes required for genome replication.

Transcription of intermediate and late genes is controlled by the binding of specific viral proteins to characteristic promoter sequences. Virion assembly occurs in circumscribed

areas of the cytoplasm. Intracellular mature virus moves to the vicinity of the *trans*-Golgi network or early endosomes on microtubules and acquire a double membrane. This intracellular enveloped virus moves to the cell surface on microtubules, where the outermost membrane fuses with the plasma membrane, and the virus is released from the cell by exocytosis. Most particles, however, are not enveloped and are later released by cell disruption. Both types of particles are infectious, but the enveloped particles, which are more rapidly taken up by cells, appear to be the more important in spread of the virus throughout the body.

EPIDEMIOLOGY

Smallpox

Smallpox was once worldwide in scope, persisting as an endemic disease in areas where susceptible populations were sufficiently large to permit year-round transmission. In more remote or isolated areas, epidemics occurred only sporadically following introduction of the disease. Transmission eventually ceased when the number of susceptible contacts diminished to very low numbers because infection resulted in essentially permanent immunity. Before vaccination was practiced, almost everyone eventually contracted the disease.

The seasonal occurrence of smallpox was similar to that of varicella and measles, its incidence being highest during winter and spring. This factor was consonant with the observation that the duration of survival of the virus in the aerosolized form was inversely proportional to both temperature and humidity.<sup>52</sup> Such seasonal variation was undoubtedly amplified in many countries by social events, such as the congregation of large numbers of people during the dry season at festivals and marriage parties, and the movement of nomads during this period. Where there was less variation in temperature and humidity, as in equatorial areas of Indonesia and Congo, there was little discernible fluctuation in incidence throughout the year.

There were also longer-term trends in incidence in the endemic areas, which resulted in major epidemics at intervals of 4 to 7 years,<sup>1,53</sup> presumably relating to the pace of accumulation of susceptible people.

Within the household, smallpox was as infectious as chickenpox but less infectious than measles.<sup>54–56</sup> With few exceptions, however, smallpox spread less widely and rapidly than

these diseases. This finding can be accounted for by the fact that transmission of smallpox virus did not occur until onset of rash, as attested by numerous epidemiologic observations. By then most patients were already confined to bed because of the high fever and malaise of the prodromal illness; secondary cases were usually restricted to the few who came in contact with them, usually in the household or hospital. On average, a given case of smallpox seldom resulted in more than two to five cases in a subsequent generation, most of whom were relatives or friends. For this reason, smallpox outbreaks tended to be clustered in a segment of a town or village and in localized areas of a province or district.<sup>57–60</sup> Most outbreaks, therefore, could be contained successfully by vaccination of a comparatively small number of residents in and near the houses in which patients lived.

The age distribution of smallpox cases depended on the acquired immunity of the population, whether by vaccination or by infection. Cases among adults were regularly found, however, even as recently as 1974 to 1975 in India, where vaccination had been widely practiced and where smallpox was endemic. During this period, 21% of a carefully documented series of 23,546 patients were older than 20 years of age, and 2% were older than 50 years of age.<sup>61</sup> In western Africa from 1967 to 1969, most cases were in rural villages, and the age distribution of cases approximated the age profile of the population.<sup>62</sup> In all countries, males and females were equally affected.

Where the Asian form of variola major was prevalent, case-fatality rates among the unvaccinated were about 25% to 30% overall (Table 58-1), but for those younger than 1 year of age, they ranged from 40% to 50%. Variola major in Africa was a milder disease, with case-fatality rates of about 5% to 15%. Variola minor, which after 1967 was present only in Brazil and southern and eastern Africa, resulted in case-fatality rates of 1% or less.

Transmission of variola virus, with few exceptions, resulted from virus-containing droplets expressed by a patient from the oral, nasal, or pharyngeal mucosa that were inhaled by susceptible persons in close contact with the patient. Such transmission was possible from the time of onset of rash and was most frequent during the first week of the exanthem. Virus was also present in high titer in scabs that had separated from the skin lesions.<sup>63</sup> Epidemiologic evidence, however, showed that infected scabs played a negligible role in transmission of infection, presumably because the virus was tightly

bound in its fibrin matrix. It was standard practice, nevertheless, during the global eradication program, to isolate patients until all scabs had separated from the skin. Airborne infection over longer distances was uncommon, although two outbreaks within hospitals demonstrated this to be possible.<sup>61,64</sup> The infection of persons such as laundry workers who handled linen from patients has also been repeatedly documented.<sup>9</sup> However, various older accounts that purport to document transmission over great distances on other fomites, such as carpets, letters, and cotton rags, are suspect because the virus does not survive for long periods at customary ambient temperatures.<sup>65</sup>

## Monkeypox

Monkeypox was first identified as the cause of illness in captive monkeys in a research facility in Copenhagen in 1958.<sup>66</sup> The first human cases were identified in 1970. The epidemiology of monkeypox differs substantially from that of smallpox. Until 2003, when the first outbreak of monkeypox occurred in the Western Hemisphere, the disease caused only sporadic cases in central and western Africa and one outbreak of uncertain size in the Democratic Republic of the Congo.

Between 1970, when the first human cases of monkeypox were identified, and 1981, national surveillance programs detected 67 cases of monkeypox in six countries: Cameroon (2), Ivory Coast (2), Liberia (4), Nigeria (3), Sierra Leone (1), and Congo/Zaire.<sup>55</sup> Concerned as to whether monkeypox could possibly be sustained by direct human-to-human transmission, WHO and Zaire staff undertook a greatly intensified surveillance program between 1981 and 1986 to better define the epidemiology of the disease. In all, 338 additional cases were detected in Zaire, and during this period 6 cases occurred in the Central African Republic (Fig. 58-2).

The studies in Zaire revealed that there was a natural reservoir host for the virus in ground squirrels (genera *Funisciurus* and *Heliosciurus*) and perhaps other rodents and that humans and monkeys were incidental victims and did not readily transmit infection to others.<sup>67</sup> With the cessation of

these studies, surveillance activities decreased sharply, and only occasional suspect cases were subsequently reported until 1996.

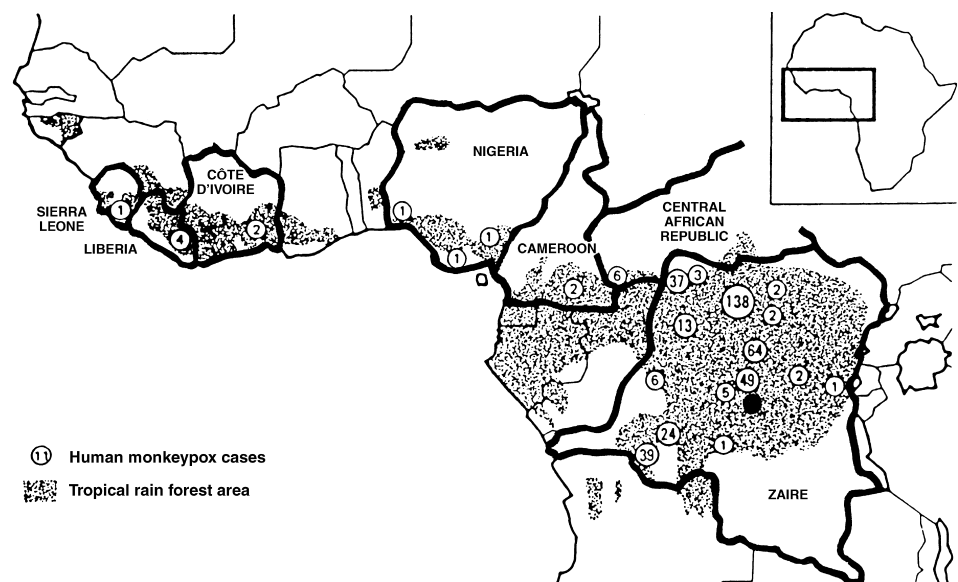

As yet, the most reliable and comprehensive epidemiologic data derive from the 1981 to 1986 field studies conducted in 17 health zones of three regions of Zaire (Equateur, Bandundu, and Kasai Oriental).<sup>2</sup> Seventy percent of the patients lived within 100 m of the edge of the rain forest. There was no apparent seasonal trend.

The 338 cases (of a total of 404 recognized in Africa during this period) occurred in 203 separate outbreaks, of which 132 were single cases only. The other cases occurred in outbreaks of between 2 and 7 cases. An animal source of infection was suspected for 245 cases, 42 of which were coprimaries.

Apparent human-to-human spread of infection occurred much less frequently than with smallpox. In all, there were 69 second-generation cases, 19 in the third generation, and 5 fourth- and fifth-generation cases. All were close contacts: 71 household contacts, 10 relatives or neighbors living nearby, and 12 others living in neighboring villages. Only 40 (10%) of 431 unvaccinated household contacts who lived in the confined, poorly ventilated huts developed monkeypox (Table 58-2). Most patients were unvaccinated young children. Forty-three who had been previously vaccinated developed disease, of whom 60% developed "mild" or "moderate" disease in contrast with 26% of the unvaccinated<sup>3</sup> (Table 58-3). Contacts between patients and wild animals within the 2 to 3 weeks preceding illness were frequent and diverse and included several species of monkeys, rodents, and antelope. However, based on extensive ecological studies in different areas of Zaire, it appears that the primary reservoir is ground squirrels. Indeed, wherever cases of monkeypox were documented, the residents normally trapped and consumed squirrels, and in a southern study area where rodents were seldom eaten, monkeypox cases were rare.

The active surveillance program ended in 1986. Between 1986 and 1992, only 13 cases of human monkeypox were reported in Africa; no cases were reported between 1993 and 1995.<sup>48</sup>

From Jezek Z, Fenner F: Human monkeypox. In Melnick JL (ed): Monographs in Virology, No. 17. Basel, Karger, 1988.

In July 1996, a sizable outbreak of monkeypox was reported from the Katano-Kombe health zone, Kasai Oriental region in central Zaire.<sup>3</sup> Initial investigations by WHO, the Congolese, and international teams discovered 92 possible cases in 12 villages, with onsets between February 1996 and February 1997. Three persons died. Studies, however, had to be interrupted because of civil disorder. How many of the cases were caused by monkeypox virus infection and how many were caused by varicella is uncertain. Comparatively few cases were seen during the acute phase of illness, and few specimens were tested. There was general concern, however, that monkeypox might spread with greater facility in a population where vaccination had ceased in the 1970s. In October 1997 an additional 419 cases of vesiculopustular disease were detected.<sup>68</sup> The low case-fatality rate (1.5%) and the high secondary transmission rate (78%) sharply distinguish these most recent outbreaks from those prior to this time. Given the facts that varicella spreads readily from person to person and is associated with a low case-fatality rate, the observations are best explained as a mixed epidemic composed primarily of varicella cases with a scattering of monkeypox infections.

In the spring of 2003, monkeypox emerged for the first time in the Western Hemisphere. The outbreak affected 72 persons (37 were laboratory confirmed) in the central United States (<http://www.cdc.gov/od/oc/media/mpv/cases.htm>). People developed a febrile rash illness after close contact with sick

pet prairie dogs and other mammals. No one died. The probable introduction of monkeypox into the United States occurred during a shipment of small mammals (which included African rodents) from Ghana to Texas.<sup>49</sup> Sick animals were subsequently transported to a Chicago area pet distributor via an Iowa animal vendor. In Chicago, sick animals were cohoused with prairie dogs that were subsequently transported to a vendor in Wisconsin and sold to the index patient and others. All cases appear to have resulted from close contact with infected prairie dogs. Although some patients were also household contacts of affected people, no cases of monkeypox could be attributed exclusively to person-to-person contact. There were no secondary cases in this outbreak. However, strict infection control measures were undertaken, which included pre- and postexposure vaccination of potentially exposed people with smallpox vaccine. In all, 30 persons received smallpox vaccine; 7 preexposure and 23 postexposure.<sup>69</sup>

**DISEASES**

Smallpox and monkeypox have an incubation period of about 12 days, with a range of 7 to 17 days. A 2- to 5-day period of high fever, malaise, and prostration with headache and backache is followed by the development of a maculopapular rash. The rash appears first on the mucosa of the mouth and pharynx, the face, and the forearms, and spreads to the trunk and legs. Within 1 to 2 days, the rash becomes vesicular and then pustular. The pustules are characteristically round, tense, and deeply embedded in the dermis; crusts begin to form about the eighth or ninth day. When they separate, they leave pigment-free skin and, eventually, pitted scars. The eruption is characteristically more extensive on the face and distal parts of the arms and legs, and lesions are occasionally found on the palms and soles (Figs. 58-3 and 58-4).

Illness caused by variola major was generally more severe, with a more extensive rash, a higher fever, and a greater degree of prostration than illness caused by variola minor. A milder form of disease was also seen among those who had previously been vaccinated, the rash in such persons tending to be more scant and atypical and the evolution of lesions more rapid.

Cases of smallpox among pregnant women often resulted in spontaneous abortion of the fetus or a stillborn infant with evidence of lesions on the skin. One congenital monkeypox infection has been reported: a child born in the seventh month of pregnancy with generalized skin lesions. The child recovered from infection but died of malnutrition at 7 weeks of age.<sup>2</sup> The principal distinguishing characteristic of monkeypox is the temporary enlargement of lymph nodes seen in African patients in 86% of unvaccinated patients and 54% of those previously vaccinated.<sup>2</sup> In the U.S. outbreak of 2003, lymphadenopathy was present in approximately 47% of the first 30 cases reported.<sup>70</sup> Most cases exhibit generalized lymphadenopathy; about a fourth exhibit lymphadenopathy only in one or two areas—in the submaxillary, cervical, axillary, or inguinal regions. The lymphadenopathy typically develops coincident with or shortly after the onset of the prodromal fever, occasionally 1 or 2 days after the onset of rash. The nodes are 1 to 2 cm in diameter and are firm, tender, and occasionally painful. In most cases, there is edema of the surrounding subcutaneous tissue. Abscess formation occurs in a few cases.

**FIGURE 58-3** A, Smallpox day 2: papules in the same stage of development. Papules are usually seen first on the face and subsequently on the body and extremities; they eventually form vesicles. B, Smallpox day 5: the fluid in the vesicles becomes cloudy and looks like pus. At this stage, the pocks are called pustules. C, Smallpox day 8: around day 8 of rash, the pustules are firm to the touch and deeply embedded in the skin. Pustules gradually dry up and form scabs that eventually fall off. (Courtesy of the World Health Organization, Geneva. Available at <http://www.who.int/emc/diseases/smallpox/slideset/>.)

Of the 338 monkeypox cases observed during the Zaire studies, complications occurred in 122, almost all among the unvaccinated.<sup>2</sup> Sixteen percent of the unvaccinated patients experienced secondary infection of their lesions with boils, cutaneous or subcutaneous abscesses, and septic dermatitis. Pulmonary distress and bronchopneumonia occurred late in the course of illness in 34 patients (10%), of whom 19 died. Vomiting and diarrhea leading to severe dehydration occurred in 8% and corneal ulceration in 4% of patients.

Death as a result of smallpox virus infection usually occurs late in the first week or during the second week of the illness and is commonly due to the effects of an overwhelming viremia. Occasionally with smallpox, a severe and always fatal hemorrhagic form occurs, with extensive bleeding into the skin and gastrointestinal tract, followed by death within a few days. Such hemorrhagic cases have not been observed with monkeypox. Among the 338 monkeypox cases in the 1981 to 1986 Zaire study, there were 33 deaths, a case-fatality rate of 9.8%. All were unvaccinated children between 3 months and 8 years of age. There were no deaths among the 72 cases in the U.S. outbreak of 2003.

**FIGURE 58-4** Monkeypox. Disseminated monkeypox skin lesions. As in smallpox, these lesions evolve from papules to vesiculopustules, which crust and detach. (Courtesy of Drs. E. Stratman, K. Reed, and J. Melski, Marshfield Clinic, Marshfield, WI.)

## **PATHOGENESIS AND IMMUNITY**

It is presumed that in humans the pathogenetic and immune responses to smallpox and monkeypox are essentially the same. Natural infection occurs following implantation of the virus on the oropharyngeal or respiratory mucosa.<sup>1</sup> Virions in droplets expressed from nasal and oropharyngeal secretions are far more infectious than those bound in the fibrin mesh of scabs. After migration to and multiplication in regional lymph nodes, an asymptomatic viremia develops around the third or fourth day, followed by multiplication of virus in the spleen, bone marrow, and lymph nodes. A secondary viremia begins around the eighth day, accompanied by fever and toxemia. The virus, contained in leukocytes, then localizes in small blood vessels of the dermis and beneath the oral and pharyngeal epithelium and subsequently infects adjacent cells. In the skin, this process results in the characteristic maculopapular lesions and, later, the vesicular and pustular

lesions, which, for reasons unknown, are more extensive on the face and distal extremities. Lesions in the mouth and pharynx ulcerate quickly because of the absence of a stratum corneum, releasing large amounts of virus into the saliva about the time the cutaneous rash first becomes visible. Virus titers in saliva are highest during the first week of illness, corresponding to the period during which patients are most infectious.

Hemagglutinin-inhibiting (HI) and neutralizing antibodies can be detected beginning around the sixth day of illness, or about 18 days after infection, and complement-fixing (CF) antibodies approximately 2 days later.<sup>71–73</sup> Neutralizing antibodies are long-lasting, whereas HI antibodies decline to low levels within 5 years, and CF antibodies rarely persist for longer than 6 months. Little is known about the development of cell-mediated immunity.

The genome of variola virus revealed DNA sequences that would not have been understood at the time of the eradication of smallpox. Numerous viral proteins resemble cytokine receptors or binding proteins that antagonize the effects of gamma interferon, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-1 $\beta$ , IL-18, and CC chemokines. The theme of viral inhibition of host immunity is also evident in variola proteins that bind C4a and C3b and inhibit complement activation, bind double-stranded RNA preventing activation of protein kinase PKR and 2.5A synthetase, and inhibit caspase-mediated TNF- and Fas-induced apoptosis.

Except for the lesions in the skin and mucous membranes and lymphoid hyperplasia, other organs are seldom involved. Secondary bacterial infection is not common, and death, when it occurs, probably results from the toxemia associated with circulating immunocomplexes and soluble variola antigens.<sup>74,75</sup> With smallpox, encephalitis sometimes ensues that is indistinguishable from the acute perivascular demyelination observed as a complication of infection due to vaccinia, measles, and varicella.

As the patient recovers, the scabs separate and the characteristic pitted scarring gradually develops. The scars are most evident over the face and result from the destruction of sebaceous glands followed by contraction of granulation tissue and fibrosis.

## DIAGNOSIS

Most cases of smallpox and monkeypox can be diagnosed readily by the appearance of the typical deep-seated rash, the centrifugal distribution of lesions, and the fact that, on any given area of the body, all lesions are at the same stage of development. With smallpox, hemorrhagic cases were often initially misdiagnosed as meningococcemia, acute leukemia, or drug toxicity, but their identity was soon established by examining other patients who were the source of infection or to whom disease had been transmitted. Varicella was by far the most frequent disease to be confused with smallpox or monkeypox. Patients who had previously been vaccinated and those with variola minor sometimes exhibited a sparse and atypical rash with minimal systemic symptoms that resembled varicella; some severe cases of varicella in adults with extensive rash were also mistaken for smallpox.<sup>76</sup>

The methodology for the laboratory diagnosis of poxvirus infections has recently been reviewed by Damon and Esposito.<sup>77</sup> Diagnosis of poxvirus infection is confirmed rapidly by electron

microscopic identification of virus particles in vesicular or pustular fluid or scabs. A suspected case of smallpox or monkeypox should be immediately reported to the relevant public health agency. All *Orthopoxvirus* virions have the same appearance, a distinctive brick-shaped knobby morphology, one which is shared by the virions of molluscum contagiosum and tanapox. The orthopoxviruses grow and produce a cytoplasmic effect in cultured cells derived from many species, although they generally grow best in cells from humans and other primates. The four orthopoxviruses that infect humans (variola, vaccinia, cowpox, and monkeypox), however, cannot be differentiated readily from one another in most cell cultures. For diagnostic purposes, they are customarily grown on the chorioallantoic membrane (CAM) of 10- to 12-day-old chick embryos on which they produce pocks characteristic of their species. Other biologic assay methods include reproductive ceiling temperatures in cell cultures or on CAM, and lethality or infectivity for various animals or animal tissues.

Each species of *Orthopoxvirus* has a distinctive DNA map demonstrable by polymerase chain reaction (PCR) amplification of various genome DNA segments followed by restriction endonuclease assays of the amplicons. Another PCR method uses primers targeting the gene sequence encoding the hemagglutinin glycoprotein, since this locus is unique to the orthopoxviruses.<sup>78</sup> Yet other PCR methods target the gene for the A-type inclusion body protein. In addition, DNA oligonucleotide microarray using the *crmB* (cytokine response modifier—a TNF receptor homologue produced by orthopoxviruses) gene as the target has been reported as a method for the identification of orthopoxviruses at the species level, since orthopoxviruses contain either a full-length or a truncated form of this gene.<sup>79</sup> A random amplified polymorphic DNA fragment length polymorphism method has also been reported.<sup>80</sup>

Recovered patients exhibit high titers of neutralizing, HI, and CF orthopoxvirus antibodies, but within a given genus, poxviruses are so closely related antigenically that it is difficult to identify the species utilizing virus neutralization tests with hyperimmune reference sera. Characteristic residual facial scars are most useful in documenting prior cases of variola major or monkeypox,<sup>1</sup> but such scars were too infrequent to be of value in identifying recovered cases of variola minor.<sup>81</sup>

## TREATMENT

There is no specific treatment for smallpox or monkeypox. In experimental studies of the action of various antiviral drugs against two strains of variola major virus, one strain of variola minor virus, monkeypox, and other poxviruses in tissue culture, three compounds showed significant inhibition patterns—cidofovir (hydroxypropyl methylcellulose phthalate, HPMP), its cyclic derivative (cyclic HPMP), and ribavirin.<sup>82</sup> The first two compounds inhibit DNA polymerase, and ribavirin inhibits inosine monophosphate dehydrogenase. Cidofovir is licensed for the treatment of cytomegalovirus retinitis in patients with acquired immunodeficiency syndrome; ribavirin is licensed for the treatment of chronic hepatitis C and respiratory syncytial virus infections. There is a single reported case of the successful use of ribavirin in the treatment of progressive vaccinia; however, it is not possible to judge the efficacy of the drug, since it was combined with vaccinia

immunoglobulin.<sup>83</sup> Mouse models of *Orthopoxvirus* infection have shown that systemic delivery of cidofovir before onset of disease can prevent a fatal outcome.<sup>84–86</sup> Unfortunately, drug administration after disease onset has proved disappointing (P. Jahrling, personal communication, 2003). Further studies are in progress at the U.S. Army Medical Research Institute of Infectious Diseases and the CDC. The CDC currently holds an investigational new drug protocol for the use of cidofovir in the treatment of smallpox, certain vaccinia complications (i.e., severe generalized vaccinia, eczema vaccinatum, or progressive vaccinia) (<http://www.bt.cdc.gov/agent/smallpox/vaccination/cidofovir.asp>), and severe monkeypox infection (<http://www.cdc.gov/ncidod/monkeypox/treatmentguidelines.htm>). The drug must be administered intravenously and is associated with considerable toxicity. An orally available formulation is under development.<sup>87</sup>

Supportive therapy, maintenance of fluids and nutrition, and good nursing care are the best that can be offered to most patients. Such care for suspect smallpox patients could most safely be provided by people who have recovered from smallpox (as smallpox reinfections are virtually unknown), but few such individuals are now available. Note that health-care workers can be protected from disease even when vaccinated two to three days after exposure and protected from a fatal outcome when vaccinated as long as four to five days after. Thus, all who care for patients should be vaccinated or revaccinated before exposure to patients or as soon thereafter as possible. Those who bear a scar from previous vaccination are preferred because of the more rapid development of protective immunity after revaccination. Similar precautions in providing care for monkeypox cases are probably called for but are less essential given the diminished likelihood of human-to-human transmission of monkeypox.

The skin lesions, although pustular, do not usually contain bacteria, and in fact, secondary bacterial infections are uncommon under most circumstances.<sup>9</sup> To accelerate the clearing of skin lesions and to minimize scarring, all manner of treatments have been devised ranging from physical abrading of the pustules to painting of the skin with gentian violet. None proved useful.

## PREVENTION AND CONTROL

### General Preventive Measures

With smallpox eradication confirmed and no cases for more than 25 years, preventive measures against smallpox should not be needed. However, an increase in international terrorism and the growing threat of biological weapons pose special problems with respect to smallpox. Likewise, preventive measures against monkeypox have been deemed unnecessary given the fact that cases have been few and that the 1980s studies in Zaire showed that the virus spread only with difficulty from person to person. Recent events, however, have challenged both positions.

Of special concern is the possibility that smallpox virus might be disseminated deliberately and so have the opportunity to reestablish itself. So far as is known, stocks of smallpox virus are presently retained at only two WHO-authorized laboratories: in the United States at the CDC, Atlanta; and in Russia, at Vektor Laboratories, Koltsovo, Novosibirsk.

However, it is impossible to state with certainty that no other stocks exist either in Russia or in other countries. Destruction of the authorized stocks of virus had been recommended by a WHO Expert Advisory Panel,<sup>88</sup> was endorsed by a number of international and national microbiological societies and advisory groups, and at one time, approved by the World Health Assembly (WHA) to take place in June 1999. However, continuing debate by those favoring and those opposing this action resulted in a decision to postpone destruction of the virus pending further studies, which some have believed might eventuate in an improved vaccine or antiviral therapy.<sup>89,90</sup> Meanwhile, the WHA has approved studies of the virus only in the two WHO-designated laboratories, both of which are to be regularly visited by international teams to assure biological security; protocols for all studies are to be reviewed by a WHO expert group.

Should smallpox cases once again occur, the potential for epidemic spread is great. Because vaccination programs ceased in 1980, there are very large numbers of people who have never been vaccinated and large numbers of adults with waning immunity. Thus, the early detection of suspect smallpox cases represents a major public health emergency requiring immediate and thorough investigation by national and international authorities. National health authorities and WHO should be notified promptly, specimens of pustular fluid and scabs should be collected in screw cap glass bottles, and patients should be isolated in their houses or in special isolation facilities set aside for this purpose. Special attention should be paid to severely ill patients who experience bleeding into the skin such as one might see with severe meningococcemia. Such patients will not have the typical smallpox rash but may be experiencing the highly transmissible, always fatal, hemorrhagic form of smallpox and should be isolated with particular care.

Specimens from patients need to be processed at specially equipped laboratories whose proficiency has been certified by WHO. Should vaccine be required, limited supplies could be obtained from the WHO stockpile or one of several national stockpiles. However, the quantities of vaccine available are limited and would need to be used with discretion.

The question of appropriate preventive measures against monkeypox is being kept under review. Based on the information available to date, the WHO Expert Committee on Smallpox has advised that no special preventive measures be taken with respect to vaccination in the enzootic areas. However, continuing surveillance and investigation of outbreaks has been advised as the virus is transmissible from person to person, and levels of vaccine-induced protective immunity are declining. Balancing the possible benefits of protective vaccination are several factors: the very low incidence of monkeypox; the possibility of adverse reactions to smallpox vaccine; and difficulties in conducting a vaccination program throughout the large, sparsely populated rain forest areas where roads are few and often impassable.

### Smallpox Vaccine

Smallpox vaccine (vaccinia virus, an *Orthopoxvirus*) provides durable protection against infection due to the other principal orthopoxviruses to which humans are susceptible, notably, variola, monkeypox, and cowpox. Although the vaccine virus is generally assumed to be a descendent of one or more

cowpox strains used by Jenner at the turn of the nineteenth century, the vaccinia virus strains today are clearly a species of *Orthopoxvirus* with distinctive DNA maps that are similar to each other but very different from both cowpox and variola. That the vaccinia strains are not mutants of variola virus seems certain,<sup>91</sup> but where the present vaccinia species arose is unknown. It is possible that the species represents a laboratory survivor of a now naturally extinct species of *Orthopoxvirus*, perhaps horsepox.<sup>92</sup>

Many strains of vaccinia, known by different names, have been used by different producers during this and the past century, but little is known about their origins or passage histories. Characterization of strains is further complicated by the fact that a seed lot system for vaccine production was not used until the 1960s. Thus, even those strains with common names and ancestors have different passage histories, having been passed sequentially through a variety of vaccinifers, such as cows, sheep, and water buffalo, with periodic passages through rabbits, horses, and even humans. Most of the existing stocks of vaccine derive from one of four strains: (1) the Lister strain from the Lister Institute, England, which during the 1960s and 1970s was used for production by most producers except those in the Americas, China, and India; (2) the New York Board of Health (NYBOH) strain, which was used throughout the Americas; (3) the Temple of Heaven strain used in China; and (4) the Patwadanger strain used in India.<sup>1</sup> However, there are today only a few manufacturers now capable of producing smallpox vaccine on a commercial scale.

Smallpox vaccine traditionally was grown on the skin of a calf and harvested after sacrifice of the animal. The vaccine was purified by the addition of fluorocarbon and differential centrifugation, and its bacterial content was reduced by the addition of phenol. Peptone was added as a stabilizing agent, and the vaccine was freeze-dried. Because of its source, the vaccine inevitably contained some bacteria, but the number of bacteria was usually 10 or less per milliliter. Microbiological examination routinely confirmed that none is a human pathogen. For reconstitution of the vaccine, a solution of 50% (v/v) glycerin in McIlvaine solution is used.

Three cell culture vaccines have been produced and tested, one in the Netherlands, one in Japan, and one in the United States. The Netherlands vaccine developed in the 1970s consisted of Lister strain vaccinia grown in primary rabbit kidney cell cultures.<sup>93,94</sup> In studies of 45,000 Indonesian children, the vaccine compared favorably with the standard Lister strain calf lymph vaccine.<sup>95</sup> This remained an experimental vaccine and is not available today. In Japan, Hashizume and others, also in the 1970s, attenuated the Lister strain through multiple low-temperature passages and produced this vaccine in rabbit kidney cells.<sup>96,97</sup> This strain, called the LC16m8, was found to be satisfactorily immunogenic and less reactogenic than standard strains when tested in 40,000 Japanese children. Further studies of this vaccine are now in progress in Japan and the United States. In the United States, the NYBOH strain was plaque-purified and grown in Vero cells culture. Phase I and II studies, as well as animal-challenge studies using monkeypox, indicate that the vaccine is equivalent in immunogenicity to the NYBOH strain and has comparable reactogenicity. Licensure in the United States is projected in 2005. Meanwhile, several hundred million doses have been produced and are available for use in an emergency.

Freeze-dried smallpox vaccine is the most stable of currently available vaccines. The vaccine can be preserved almost indefinitely at  $-20^{\circ}\text{C}$ , and most batches can be preserved for years at  $4^{\circ}\text{C}$ . International standards require that the vaccine in its freeze-dried form maintain full potency when incubated at  $37^{\circ}\text{C}$  for one month.<sup>98</sup> Studies of vaccine produced at the Lister Institute, however, demonstrated that the vaccine retained full potency for 64 weeks when incubated at temperatures of up to  $45^{\circ}\text{C}$  and for 104 weeks at  $37^{\circ}\text{C}$ .<sup>99</sup> After reconstitution, the vaccine is much more sensitive to temperature and to exposure to direct light. During the eradication program, unused reconstituted vaccine was routinely discarded at the end of each day, although it could be preserved in this form for at least 4 weeks at  $4^{\circ}\text{C}$ .

The vaccine is inoculated intradermally using a bifurcated needle. Vaccine, as reconstituted for use, is required to have a titer of not less than  $10^8$  pock-forming units per milliliter when assayed on the CAMs of 12-day-old chick embryos. Approximately 0.0025 mL of vaccine adheres by capillarity to the tines of the bifurcated needle when it is dipped into the vaccine. The needle is positioned vertically to the skin surface, usually the lateral surface of the upper arm, and 15 rapid strokes are made. These strokes should be sufficiently vigorous so that within 20 to 30 seconds, a trace of blood appears at the vaccination site.

## Results of Vaccination

Successful primary vaccination results in virus proliferation in the basal cells of the epidermis, producing the typical Jennerian vesicle. A papule with surrounding erythema develops in 3 to 5 days, rapidly becoming a vesicle and later a pustule. It reaches its maximum size after 8 to 12 days. A scab forms that separates at 14 to 30 days, leaving a typical vaccination scar. A low-grade fever usually accompanies the development of the pustule, and swelling of the draining lymph nodes, associated with tenderness, is often observed. Viremia may occasionally occur<sup>100</sup> between the third and tenth days, and vaccinia virus can sometimes be isolated from tonsillar swabs.<sup>101</sup>

An individual's response to revaccination depends on the level of immunity. Erythema typically develops within 24 to 48 hours as a classic delayed hypersensitivity reaction. As Benenson<sup>102</sup> has shown, this reaction can be elicited with both live and inactivated vaccine. People with some residual cell-mediated immunity, but not enough to inhibit viral replication, evidence erythema at the site and development of a vesicle and sometimes a pustule that evolve in a sequence more rapid than that in a primary vaccination reaction. The presence of erythema at the vaccination site 6 to 8 days after vaccination is evidence that viral proliferation has taken place and that the revaccination was successful. Those with substantial immunity may experience no more than the hypersensitivity reaction.

Because it is impossible to distinguish between a hypersensitivity reaction due to the use of impotent vaccine and a similar reaction due to a high level of immunity, the WHO Expert Committee on Smallpox<sup>103</sup> recommended that such a response be termed an *equivocal reaction*. Repeat vaccinations were advised for people with equivocal reactions.

Following primary vaccination, neutralizing and HI antibodies develop by the tenth day and are present in almost all

people by the end of 2 weeks; CF antibodies develop in fewer than half of the vaccinees.<sup>72</sup> Because the antibody response following primary vaccination usually occurs 4 to 8 days earlier than the response after naturally acquired smallpox infection,<sup>104</sup> primary vaccination even after exposure could modify or abort an attack of smallpox. The neutralizing antibodies are most persistent and may be detected for 20 years or more; HI and CF antibodies, however, are usually not detectable beyond 6 months. Antibody response after revaccination is more rapid, usually within 7 days, and antibody titers are generally higher. However, some people who exhibit a substantial rise in neutralizing antibody titer after revaccination fail to exhibit a rise in either HI or CF antibody levels.

Little is known about the cell-mediated immunity that is induced. Pincus and Flick<sup>105</sup> demonstrated the beginning development of delayed hypersensitivity, an index of cell-mediated immunity, as early as 2 days after vaccination. In a trial designed to evaluate the immunogenicity of undiluted and diluted smallpox vaccine in primary vaccinees, the development of a vesicle after vaccination correlated with the development of vaccinia virus-specific cytotoxic T-cell responses.<sup>106</sup> Conversely, the absence of a primary skin vesicle after primary vaccination was associated with the lack of T- or B-cell responses.

Reliable data are surprisingly sparse concerning the efficacy and durability of protection afforded by vaccination. A study conducted in 2003 measured antibody and T-cell mediated immune responses to vaccinia in volunteers examined 1 month to 75 years after vaccination.<sup>107</sup> In that study, vaccinia-specific T-cell memory declined slowly, with an estimated half-life of 8 to 15 years; vaccinia-specific antibody responses were maintained in the same range as that observed between 1 and 7 years after vaccination. The authors concluded that vaccine protection is more substantial and long-lasting than previously believed. Unfortunately, specific correlates of immunity to variola are not known because sophisticated laboratory methods to study them were not available during the time in which the disease was endemic.

Before 1967, when the intensified global eradication program began, revaccination every 3 to 10 years was considered essential to ensure protection. In part, this practice was based on early data largely from the United Kingdom, such as those provided by Hanna,<sup>108</sup> and on more recent data from India,<sup>109</sup> which compared the frequency of cases among those with and without vaccination scars. However, the vaccine in use in the populations studied was far lower in titer than that used after 1967. Moreover, most of the vaccine was heavily contaminated with bacteria and even in the absence of virus could induce infection and a scar resembling that following successful vaccination. Another observation suggesting that protection might persist for no more than 3 to 5 years was the increasing proportion of people who exhibited a major reaction to revaccination beginning about this time. Mistakenly, resistance to intradermal inoculation with vaccinia virus was equated with resistance to variola virus acquired by droplet inhalation.

From studies conducted after 1967, it became apparent that vaccinia immunity was far more durable than most investigators believed. It was found that with the available higher-titer vaccines, major reactions could be induced in people successfully vaccinated as recently as 3 to 6 months before and, indeed, in almost all of those who had experienced

smallpox only 1 year previously.<sup>110</sup> Because natural infection effectively confers permanent immunity, it was apparent that the ability of vaccinia virus to proliferate when inoculated into the basal cells of the dermis correlated poorly with the level of protection afforded against natural infection. Moreover, in most countries, 90% or more of cases were people without vaccination scars. This finding led to surveys in the endemic countries that disclosed vaccine-efficacy ratios of 80% or more among those vaccinated 20 years previously. Heiner and colleagues,<sup>56</sup> however, showed that this protection could not be attributed solely to the vaccine. They discovered that previously vaccinated persons often developed inapparent infection with substantial increases in antibody levels. Immunity in the endemic countries was thus a composite of past experiences with both vaccinia and variola infections. Data from countries where smallpox was introduced after an absence of many years provide insufficient information to permit calculation of vaccine-efficacy ratios, but they do indicate that the vaccine provides substantial long-term protection against a fatal outcome.<sup>111</sup>

It has been shown that smallpox vaccine can be administered at the same time as a number of other antigens, usually at a different site, with levels of safety and efficacy comparable to those observed when the vaccines are given separately.<sup>112-119</sup>

## Complications of Vaccination

### Skin Reactions

After vaccination, three types of abnormal skin reactions may occur, as follows: (1) eczema vaccinatum and (2) progressive vaccinia, which are both associated with abnormal host reactions; and (3) generalized vaccinia. Vaccinia virus from a lesion may also be accidentally inoculated at other sites on the body or transferred to other persons. The approximate frequency of such complications and rates per million vaccinees are shown in Table 58-4, based on a national survey by Lane and colleagues<sup>120</sup> in the United States, the only country in which comprehensive studies of this type were undertaken. More detailed prospective studies in 10 states<sup>121</sup> revealed higher rates for eczema vaccinatum, generalized vaccinia, and accidental infection, as well as for other complications; the higher rates resulted from the detection of more minor complications.

**Eczema Vaccinatum.** Eczema vaccinatum occurs in both vaccinated people and their unvaccinated contacts who have active or quiescent eczema. Either concurrent with or shortly after the development of the local vaccinia lesion, or after an incubation period of 5 days in an unvaccinated eczematous contact, a vaccinia eruption occurs at sites that are eczematous or that had previously been so. The areas become intensely inflamed, and the eruption sometimes spreads to normal skin. Constitutional symptoms are usually severe, with high temperature and generalized lymphadenopathy. Treatment with vaccinia immunoglobulin (available from the CDC) appears to reduce mortality.<sup>122</sup>

**Progressive Vaccinia.** Progressive vaccinia occurs in people who suffer from deficient immunomechanisms, such as agammaglobulinemia, defective cell-mediated immunity, or

**Table 58-4** Complications of Smallpox Vaccination in the United States, 1968\*

\*Number of reported cases (deaths in parentheses).

From Lane JM, Ruben FL, Neff JM, et al: Complications of smallpox vaccination, 1968: National surveillance in the United States. *N Engl J Med* 281: 1220–1224, 1969.

immunodeficiency associated with tumors of the reticulo-endothelial system or the use of immunosuppressive drugs. In such patients, the vaccinia lesion fails to heal; secondary lesions sometimes appear elsewhere on the body and then gradually spread. Methisazone (*N*-methylisatin  $\beta$ -thiosemicarbazone), an antiviral substance which inhibits protein synthesis, was believed to be partially effective in treatment,<sup>123</sup> but is no longer available. A recent case was treated successfully with ribavirin 20 mg/kg day in three divided doses for 5 days and vaccinia immunoglobulin.<sup>83</sup>

**Generalized Vaccinia.** With generalized vaccinia, one to many lesions develop in 6 to 9 days after vaccination at locations other than the vaccination site in otherwise healthy people. The evolution of these lesions follows the same temporal course as that of the vaccination lesion itself. Although patients may experience high fever and malaise, an uneventful recovery without the need for specific therapy is usual.

#### Accidental Inoculation

Accidental inoculation of vaccinia virus, transferred from the lesion at the vaccination site, is by far the most common, although innocuous, complication. The most common sites for inoculation are the eyelids, vulva, and perineum. Such lesions evolve rapidly and heal at the same time as the primary lesion. Accidental infection of normal contacts may also occur.

#### Postvaccinal Encephalopathy and Encephalitis

Among those without known contraindications to vaccination, postvaccinal encephalopathy and encephalitis are the

most serious complications. The incidence of these related complications was substantially higher in Europe following the use of strains in common use at that time<sup>124</sup> than in the United States, where the NYBOH strain was employed. Illness usually begins between 11 and 15 days after vaccination and is accompanied by fever, vomiting, headache, malaise, and anorexia, followed by disorientation and drowsiness and sometimes convulsions and coma. Death occurs in 10% to 35% of cases, usually within a week. Some survivors have residual paralysis or mental impairment. Paralysis, when present, tends to be of the upper motor neuron type. Among those patients who recover fully, symptoms and signs resolve within 2 weeks.

Many reports document the frequency of cases of postvaccinal encephalopathy and encephalitis in Europe and the United States, but comparison of rates is difficult because of differing criteria for diagnosis and variability in the completeness of reporting. The usual levels of incidence, such as those reported from the Netherlands,<sup>125–127</sup> Germany,<sup>126,128,129</sup> and Austria,<sup>130</sup> were higher than those in the United Kingdom,<sup>126</sup> and these rates in turn were higher than those in the United States.<sup>101,102,114</sup> Whatever the criteria and methods, differences between the rates caused a number of countries to begin using the Lister strain, then in use in the United Kingdom. A dramatic reduction in the incidence of postvaccinal encephalitis subsequently occurred.<sup>125,131</sup>

#### Myopericarditis

Because of the threat of smallpox being used as a biological weapon, vaccination of U.S. military personnel and some health-care workers began in 2002. From December 2002 to

May 2003, approximately 450,000 military personnel were vaccinated against smallpox, of whom 37 experienced acute myopericarditis. Eighty-seven percent were men, 70.5% were primary vaccinees, and the median age was 26 years. Beginning between 7 and 19 days postvaccination, some vaccinees developed chest pain and signs of myopericarditis, including typical electrocardiographic changes, elevated cardiac enzymes, and/or depressed cardiac function on imaging studies. Only one patient developed severe heart failure, and there were no deaths.<sup>132,133</sup> The findings paralleled those reported in 1983 by Finnish investigators. Finnish military personnel given the Finnish strain of vaccine are reported to have developed myopericarditis at a rate of approximately 100 per million vaccinees.<sup>134</sup> In the U.S. civilian smallpox vaccination program, there were 15 cases of myopericarditis among approximately 36,000 vaccinated. In contrast to the military program, 90% were revaccinees, 71% were female, and the median age was 48 years. Again, no fatalities were reported.

### Other Types of Heart Disease

Nine cases of heart-related incidents, such as angina and myocardial infarction, among health-care workers vaccinated in the United States in 2003 were reported. However, there is no evidence that any were causally related. Six of the nine reported having a history of ischemic heart disease prior to vaccination, and only one had no recognized cardiac disease risk factor prior to vaccination.<sup>135</sup> Further studies are in progress. Meanwhile, people with known heart disease or with three or more cardiac risk factors have been asked to defer vaccination for the present time.

### Indications for Vaccination

In endemic countries, which, until after World War I, consisted of most of the world, vaccination was recommended for everyone, with revaccination every 3 to 10 years. The only exceptions were infants, for whom primary vaccination was customarily delayed until 3 to 12 months of age, mainly because of more frequent vaccination failures at an earlier age. As higher-titer vaccines became available in the 1920s, French and then German physicians showed that a high proportion of successful vaccinations could be achieved at birth, and in some hospitals, this became routine practice,<sup>136</sup> as it did in some parts of the United States.<sup>137</sup>

As time passed and the incidence of smallpox declined, it became increasingly common for smallpox-free countries to delay primary vaccination until children were older. This resulted in part from the demonstration that maternal antibody inhibited virus proliferation<sup>137</sup> and in part from the belief that older children could better cope with the fever and systemic symptoms of vaccinia infection.

Vaccination at a later age was also less likely to be associated mistakenly with other events, such as sudden infant death syndrome, which might be temporally but not causally related. Some European countries recommended that vaccination be delayed until the second year of life to avoid postvaccinal encephalopathy, and the United States adopted the practice of vaccinating at 12 months of age, when studies suggested a higher frequency of postvaccinal encephalitis among those vaccinated at less than 1 year of age than among those vaccinated

between 1 and 4 years of age.<sup>120</sup> What these changes in policy may have achieved, however, is unknown, because no studies were performed to validate that complications were subsequently less frequent.

As a rule, most vaccination practices in the developing countries tended to parallel those in Europe and North America, and as of 1967 most countries, even those with endemic smallpox, delayed vaccination until the child was 3 to 9 months of age. Notable exceptions were Hong Kong,<sup>114</sup> where neonatal vaccination had been traditional at least since World War II, and Madras, India,<sup>109</sup> where neonatal vaccination was introduced in the late 1950s. During the late 1960s, it became apparent that vaccines that met international standards of potency consistently resulted in high levels of vaccination "takes" in newborns. Thus, newborn vaccination was recommended for all countries, although not all countries followed the practice.

Primary vaccination was provided for adults if required, although many workers considered it to be associated with a substantially higher incidence of postvaccinal encephalitis. Earlier European data suggest this to be the case,<sup>124</sup> but this was not borne out in studies conducted in the United States.<sup>120,138</sup> A review of U.S. military medical records between 1946 and 1962, conducted by the CDC, revealed no cases of central nervous system complications among an estimated 2 million recruits who were given primary vaccinations.

Since 1980 routine vaccination of the general population has ceased in all countries. Vaccination is still recommended for those working in laboratories where orthopoxviruses are used. A few countries now provide vaccination to military forces as a protection in case variola virus is used as a biological warfare agent. In addition, several countries, including the United States, the United Kingdom, and Israel, have resumed vaccination of selected members of the population, such as health-care workers, public health practitioners, and emergency first responders, who might be at higher risk of coming in contact with a smallpox patient by virtue of their professions if the virus were used as a bioterrorism agent. Since 2003, the United States has vaccinated approximately 39,500 such persons in the first phase of its smallpox vaccination program. The effort to vaccinate additional healthcare workers has waned because of concerns about possible complications from prospective vaccinees.

### Contraindications to Vaccination

During campaigns in areas that were endemic for smallpox, WHO recognized no contraindications to vaccination for two reasons: (1) the risk associated with smallpox infection was significantly greater than the risk of complications, and (2) most vaccinations were performed by people without medical training who could not be expected to recognize conditions such as eczema or to identify patients with immunodeficiency syndromes. In nonendemic areas, four conditions were generally accepted as contraindications:

1. Immune disorders included agammaglobulinemia, hypogammaglobulinemia, neoplasms affecting the reticuloendothelial system, and compromised immune status associated with the use of immunosuppressive drugs. People with such disorders, if vaccinated, were at substantial risk of developing the frequently fatal progressive vaccinia.

2. People with active eczema or a past history of eczema were at special risk of developing eczema vaccinatum, a serious and sometimes fatal complication. Because family members with eczema were also at risk of contact spread of vaccinia, it was recommended that either the healthy vaccinee or the eczematous family member live apart from the family until the lesion had fully scabbed over.
3. Pregnant women were not vaccinated on the general principle that immunization of any sort should be avoided during pregnancy and because of the rare risk of fetal vaccinia.
4. Many countries recognized as contraindications disorders of the central nervous system in potential vaccinees and sometimes their families, hoping in so doing to minimize the risk of postvaccinal encephalitis. However, there is no evidence that the exclusion of such persons affected the incidence of that complication.

## ACKNOWLEDGMENT

The material pertaining to smallpox and vaccinia is derived in large part from the chapter Smallpox and Vaccinia by D. A. Henderson, Luciana Borio, and Michael Lane in *Vaccines*, edited by S. Plotkin and W. Orenstein, published by WB Saunders in 2004. The material is reproduced with the permission of Saunders.

# Respiratory Tract Viral Infections

EURICO ARRUDA  
OTAVIO A. L. CINTRA  
FREDERICK G. HAYDEN

## INTRODUCTION

Acute respiratory infections (ARIs) are prevalent worldwide<sup>1</sup> and rival diarrhea as the leading cause of death in developing countries.<sup>1,2</sup> In some impoverished urban populations in South America, ARI symptoms may be present on an almost continuous basis, making it difficult to determine symptom-free days and estimate attack rates.<sup>3,4</sup> Children from these areas may spend 40% to 75% of their time with respiratory symptoms,<sup>1,5</sup> mostly caused by upper respiratory infections (URIs). The most striking disparity between developing and developed countries with regard to ARI epidemiology is the case-fatality rate of lower respiratory infection (LRI), mainly pneumonia, bronchiolitis, and influenza,<sup>6,7</sup> in children under 5 years of age, which may reach 16% in some areas.<sup>1,8</sup>

Several community-based studies have established the importance of common respiratory viral infections in tropical countries<sup>5</sup> (Table 59-1). In impoverished populations, these common viral infections may occur simultaneously with measles, diarrhea, and malnutrition, resulting in complex interactions of pathologic conditions that carry the potential to become life-threatening diseases.<sup>1,9</sup> Unlike certain pathogens restricted to tropical areas, the respiratory viruses have worldwide distribution, efficient person-to-person transmission, and an impact on all age groups. Except for a few agents (e.g., adenoviruses, severe acute respiratory syndrome [SARS] coronavirus) and rare cases of extrapulmonary dissemination with other respiratory viruses, replication is generally restricted to the respiratory mucosa of humans.

In most health-care facility-based studies of acute LRI (ALRI) conducted in tropical countries (Table 59-2), respiratory syncytial virus (RSV) is the virus most frequently detected (11% to 33%), followed by parainfluenza viruses (1% to 13%), adenoviruses (2% to 34%), and influenza viruses (1% to 4%). With few exceptions, human rhinovirus (HRV) and human coronaviruses (HCoV) have not been reported frequently in studies in tropical countries,<sup>5</sup> probably because of difficulties in their detection.

Although previous studies have shown that attending day-care centers can be a risk for ARI,<sup>10</sup> providing day care for children has become an important economic issue in developing countries, where mothers must join the workforce to

contribute to the family income. Consistent with studies in the United States and elsewhere, a study found a high burden of ARI in young, low-income children attending day care in Salvador, Brazil.<sup>11</sup>

Few specific interventions are available to reduce the impact of respiratory viruses,<sup>2</sup> and the application of these interventions may be further hampered by epidemiologic patterns in ARI and socioeconomic differences in temperate, developed countries compared with equatorial regions. For example, housing conditions and crowding pose challenges for optimizing health-care strategies in the tropics. While the incidences of some respiratory viruses, particularly RSV and influenza, show seasonal trends in some tropical areas, the association of seasonal peaks of respiratory viruses in general may be less apparent where fluctuations in temperature are smaller.<sup>12</sup> Nutritional and educational interventions, such as reinforcing breast-feeding,<sup>13</sup> vitamin A supplementation for measles,<sup>14</sup> and facilitation of access to oral rehydration therapy,<sup>15</sup> may have significant effect on the morbidity and mortality due to LRI alone or in association with diarrhea.

In this chapter we focus attention on the most common viral respiratory infections, whose main features are summarized in Table 59-3, and try to highlight features unique to the developing world.

## ■ Influenza Viruses

In tropical countries influenza activity may occur year-round as well as in outbreaks more typical of temperate regions. These infections cause serious disease in populations weakened by malnutrition, with limited access to medical care.<sup>16</sup> Of note, the predisposition induced by influenza to superimposed bacterial infections, mainly *Streptococcus pneumoniae*, may greatly affect morbidity and mortality, mainly among impoverished populations.<sup>17</sup> In addition, influenza viruses can reassort or sometimes cross species barriers to generate emergent strains that may cause localized outbreaks or potentially pandemics with enormous impact for health on a global scale.<sup>18</sup>

## AGENTS

Influenza viruses are pleomorphic, enveloped, with segmented negative-strand RNA genomes and belong to the family Orthomyxoviridae. Influenza viruses are distributed in three genera—A, B, and C—based on the antigenicity of the nucleoprotein (NP) and matrix protein. Influenza A virus is further classified in subtypes based on its two surface glycoproteins: hemagglutinin (HA) and neuraminidase (NA).<sup>19</sup> Among the 15 HA and 9 NA subtypes recognized in nature, 6 HA (H1, H2, H3, H5, H7, and H9) and three NA (N1, N2, and N7) subtypes have now been identified in human isolates of influenza A viruses.<sup>18</sup> However, only three subtypes of HA (H1, H2, and H3) and two of NA (N1 and N2) have caused pandemics and sustained circulation in human populations in recent years.<sup>20</sup> The genomes of influenza viruses contain eight RNA segments in influenza A and B viruses, and seven RNA segments in influenza C.<sup>19</sup>

The glycoprotein HA is responsible for the attachment of the virus to sialic acid-containing cell receptors, and it

\*Investigational use.

mediates fusion and penetration. Proteolytic cleavage of HA by cellular serine proteases exposes hydrophobic fusion domains that mediate membrane fusion. The NA cleaves terminal sialic acid from glycoconjugates present on respiratory mucins, cells, and progeny virions. This action destroys receptors recognized by HA and allows budding virus to be released from infected cells and to spread within the respiratory tract. Influenza C virus contains a single surface glycoprotein that binds to receptor, promotes fusion of membranes, and also cleaves sialic acid.<sup>19</sup>

Virus binding to receptor is followed by internalization into endosomes, fusion of viral and endosomal membranes, and release of the genome to the cytoplasm, from where it is transported to the nucleus. In influenza A viruses, the M2 protein serves an ion channel function that facilitates dissociation of the RNA segments from the virion interior. Transcription of the negative-strand genomic RNA into positive-strand messenger RNA (mRNA) and complementary RNA (cRNA) is mediated by a viral RNA polymerase complex in the nucleus. cRNA serves as a template for the synthesis of negative-strand virion RNA genome segments, and mRNA directs viral protein synthesis. Newly assembled nucleocapsids acquire an envelope as they bud through the cell surface. Only viruses with a full complement of genome segments are infectious.<sup>19</sup>

Influenza A viruses are primarily viruses of aquatic birds, particularly ducks and shore birds, which harbor all subtypes recognized to date. Selected subtypes naturally infect a range of terrestrial (swine, horses, humans) and aquatic (seals) mammals; influenza B virus infects humans and uncommonly seals, dogs, cats, and swine, and influenza C virus is primarily a virus of humans. Depending on the virus type and subtype, experimental infection can be induced in mice, ferrets, chickens, swine, and primates, and the viruses can be propagated in primary cultures of kidney cells, continuous cell lines (MDCK, Vero, PER.C6, and LLC-MK2), and also in embryonated hen's eggs.<sup>20</sup> The biologic property of influenza viruses to bind erythrocytes is exploited for early detection of the virus in cell culture and for the development of serologic assays by hemagglutination inhibition.<sup>20</sup> Influenza viruses are inactivated by temperatures above 50°C and by lipid solvents, acid, formaldehyde, ionizing radiation, and ultraviolet (UV) light.<sup>20</sup>

## EPIDEMIOLOGY

Influenza viruses occur throughout the world, causing highly contagious respiratory infections with high morbidity and excess mortality (in seasonal peaks), particularly in infants and the elderly. In developing tropical countries, influenza has been associated with an average of 5% of ARIs leading to physician contact.<sup>6,21</sup> This apparently low proportion probably represents only the most severe cases, since 30% to 50% of children under 5 years of age in tropical Africa have been found to seroconvert in one outbreak.<sup>21</sup> Previously healthy children younger than 1 year of age are hospitalized for influenza at rates similar to those for adults at high risk for influenza, and influenza accounts for a great number of outpatient visits and courses of antibiotics in children of all ages.<sup>22</sup> When human influenza virus is introduced into a malnourished population with limited access to care, high morbidity and mortality rates can occur, as was observed in

Madagascar in 2001 where a conventional influenza A/H3N2 subtype virus was associated with case-fatality rates of approximately 3%.

Contrary to the remarkably sharp seasonality of influenza A outbreaks in temperate countries, seasonal patterns in tropical countries have varied between studies. In southern India<sup>23</sup> and Thailand<sup>24</sup> influenza has occurred throughout the year with sporadic outbreaks, whereas there have been consistent outbreaks in June–July and November–January, coinciding with the winter seasons in the southern and northern hemispheres, but with no apparent association with meteorologic factors.<sup>12</sup> In the Philippines influenza has been more frequent between November and January,<sup>25</sup> while in Senegal, Nigeria, and Taiwan there has been clear association with increased rainfall.<sup>12</sup> In southeastern Brazil,<sup>26</sup> Argentina,<sup>27</sup> as well as in South Africa,<sup>28</sup> seasonal outbreaks of influenza A have occurred annually from May through August (mid autumn through winter) in association with cooler temperatures but not with rainfall. Influenza B outbreaks occur periodically, yet less frequently than influenza A, in both temperate and tropical regions,<sup>12,20</sup> whereas influenza C is generally nonseasonal.<sup>20</sup>

Minor changes in antigenicity, called antigenic drift, are caused by accumulation of point mutations in the genes coding for influenza HA and NA, generating new strains that spread in annual epidemics. Influenza viruses B and C are less prone to antigenic drift. Major antigenic changes in influenza A are called antigenic shift and result in the emergence of a novel HA subtype with or without new NA to which humans lack significant immunity.<sup>18</sup> This may be caused by the acquisition of new gene segments through genetic reassortment in a host infected simultaneously by a human and an animal (typically avian) virus, or by reappearance of a subtype from reservoir. Swine are susceptible to both avian and human influenza viruses and may be hosts for reassortment or serve as the mammalian species in which avian viruses can adapt. Novel influenza virus subtypes generated by shift have caused catastrophic pandemics, including three in the last century. The H1N1 “Spanish flu” pandemic of 1918 is estimated to have caused up to 100 million deaths worldwide,<sup>18</sup> while the H2N2 “Asian flu” in 1957 and the “Hong Kong flu” in 1958 caused an estimated 1 to 3 million deaths.

Recent clusters of human infections due to avian influenza, particularly H5N1 subtype viruses in Asia, have raised concerns about new pandemic threats. In 1997 a highly pathogenic avian influenza H5N1 virus resulting from reassortment among several avian viruses caused lethal outbreaks in domestic poultry and severe illness with 6 deaths among 18 human cases in Hong Kong. The outbreak was due to exposure to infected poultry in live poultry markets and was later contained by their slaughter. This virus was transmitted inefficiently from person to person.<sup>18,20</sup> In February 2003 an H5N1 virus caused deaths in a family visiting Fujian province in China. Since late 2003 wide-scale poultry outbreaks due to H5N1 virus have occurred in at least 10 Asian countries. Interspecies transmission to humans occurred in at least two countries, causing over 45 cases and 32 deaths in Vietnam and Thailand.<sup>29</sup> These H5N1 viruses have continued to reassort, evolve antigenically, and extend their host range with documented infections in swine and felids. Prolonged nonsymptomatic excretion in ducks and detection

in migratory birds indicate that this virus has become endemic in Southeast Asia.<sup>18,30</sup>

An avian H9N2 virus with human receptor specificity has also spread throughout Asia in domestic poultry and pigs and caused mild disease in humans in Hong Kong and China.<sup>18</sup> An avian H7N7 virus caused conjunctivitis in at least 82 people and one fatal pneumonia in The Netherlands in 2003; the outbreak was contained by culling and quarantine of poultry. In February 2004 a highly pathogenic H7N3 virus emerged in domestic poultry in British Columbia with two documented human cases of conjunctivitis and mild “flulike” illness.<sup>18,29</sup>

Influenza virus is transmitted from person to person by large droplets and small-particle aerosols, as well as possibly by fomites with hand contamination and subsequent self-inoculation. The relative importance of these routes is uncertain for natural influenza. Ingestion of infected birds has led to infection by avian viruses in cats. Secondary attack rates may reach over 70% in semiclosed populations, especially among schoolchildren and patients debilitated by underlying conditions who live in relative confinement, such as nursing home residents.<sup>20</sup> Children play a major role in influenza outbreaks with respect to propagation of the epidemic virus in families and communities.<sup>20</sup>

## CLINICAL FEATURES

Classic influenza starts abruptly after an incubation period of 1 to 2 days, with fever, chills, malaise, headache, myalgia, and prostration, often accompanied by nonproductive cough, sore throat, and mild rhinorrhea. Systemic complaints last 3 to 5 days, whereas sore throat, hoarseness, and cough, with substernal discomfort, may increase in severity as the systemic symptoms subside. Cough and asthenia often persist for 2 weeks or longer. Respiratory symptoms may be minimal or absent initially, especially in the elderly or infants. In frail elderly persons, lassitude, lethargy, confusion, low-grade fever, and sometimes gastrointestinal complaints may be the primary findings. Influenza B tends to be milder than influenza A, and influenza C typically causes colds or bronchitis.<sup>20</sup> Influenza may also present as unexplained fever, croup (laryngotracheobronchitis), vomiting, diarrhea, and neurologic manifestations in young children.<sup>31</sup> Up to 50% of influenza virus infections in adults are subclinical.<sup>20</sup>

Influenza causes a variety of viral respiratory complications, including otitis media, sinusitis, tracheobronchitis, pneumonia, and, in young children, bronchiolitis and croup. Secondary bacterial infections, especially pneumonia caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*, are common complications and should be suspected in relapses of fever, chest pain, and cough.<sup>20</sup> Influenza is also associated with invasive meningococcal infections. Other complications include exacerbations of asthma, chronic bronchitis, and congestive heart failure. Myositis, myoglobinuric renal failure, meningoencephalitis, transverse myelitis, polyneuritis, parotitis, myocarditis, arthritis, and disseminated intravascular coagulation rarely occur after influenza. Reye's syndrome occurs in fewer than 1 per 100,000 cases of influenza in patients under 18 years of age following the use of salicylates. Pregnant women, human immunodeficiency virus (HIV)-infected patients, and other immunocompromised hosts are at higher risk for severe disease and complications.<sup>20</sup>

## PATHOGENESIS AND IMMUNITY

The virus infects the respiratory mucosa, where it causes lytic infection of cells and desquamation of the respiratory epithelium, mononuclear cell infiltrates in the lamina propria, and altered mucociliary clearance. Tracheobronchitis is a typical feature and often associated with prolonged abnormalities in small airway pulmonary function and airway hyperreactivity. Primary influenza viral pneumonia results in diffuse alveolar damage, alveolar hemorrhage and exudate, hyaline membranes, and later reactive fibrosis. Fatal cases show pathologic changes in nonrespiratory organs, such as brain congestion and swelling, myocardial inflammation, and fibrinoid changes in arterioles.<sup>20</sup>

Viral replication in the upper respiratory tract generally peaks within 1 or 2 days of symptom onset and, depending on age and prior immunologic experience, continues for about 3 to 8 days. The severity of illness broadly correlates with upper respiratory tract viral levels. Constitutional symptoms with influenza are due in part to the release of proinflammatory cytokines and chemokines. Levels of interferon (IFN- $\alpha$  and IFN- $\gamma$ ), tumor necrosis factor (TNF- $\alpha$ ), interleukins and chemokines (IL-1 $\beta$ , IL-6, IL-8, IL-10, MCP-10, MIP-1 $\alpha$  and MIP-1 $\beta$ ) are increased in nasal secretions, and IFN, IL-6, and TNF- $\alpha$  are increased in blood in human influenza.<sup>20</sup> The tissue tropism of a strain of influenza virus depends, among other factors, on a combination of susceptibility of its HA to be cleaved by, and tissue availability of proteases with specificity to cleave it, thus rendering the virus infectious.<sup>32</sup> Extrapulmonary dissemination of virus has been uncommonly documented in humans, but systemic spread is a regular feature of highly pathogenic avian viruses in chickens and sometimes in rodents or other mammalian hosts. Serum and secretory antibodies directed to HA and NA appear about 10 days after infection. Protection against reinfection by the homologous strain is durable following natural infection and is correlated with serum and nasal neutralizing antibody levels, principally directed against HA. Vaccine-induced protection may last for up to 2 to 3 years against homotypic virus. Infection also induces cell-mediated immunity, which is detectable 3 to 6 days after infection and seems to be important for recovery.<sup>30</sup> Cytotoxic T-lymphocyte responses against internal proteins may provide some degree of heterosubtypic immunity.

## DIAGNOSIS

The diagnosis of influenza is frequently made on the basis of clinical and epidemiologic information. A higher index of suspicion and laboratory diagnostics is needed outside the season, particularly in sporadic individual cases or unexplained outbreaks of febrile respiratory illness. Viral isolation from respiratory specimens can be done in several types of cells (e.g., PRMK, MDCK, LLC-MK2) and remains the current standard.<sup>20</sup> The presence of virus may be detected in cell cultures by hemadsorption with guinea pig erythrocytes before or after cytopathic effect (CPE) is visible. Blind hemadsorption is positive 3 days after inoculation in almost all positive samples.<sup>20</sup> Confirmation of isolates can be done by hemagglutination inhibition or immunofluorescence with type-specific antisera. Diagnosis can also be made in 1 to 2 days by

immunofluorescence of monolayers of MDCK cells inoculated by centrifugation (shell-vial).<sup>33</sup> Conserved influenza antigens (M or NP) directly in clinical samples can be detected by one of several techniques (e.g., immunofluorescence [IF], enzyme immunoassay [EIA]), and multiple point-of-care kits are commercially available with turnaround time of 15 to 30 minutes. One commercial assay is based on detection of influenza-specific NA activity. The sensitivities of these assays are higher in children (up to 90%) than in adults (generally 50% to 70%) and depend on duration of illness and sample type.<sup>20</sup>

Several formats of reverse transcription–polymerase chain reaction (RT-PCR) assays have been used for the detection of influenza A and B RNAs in clinical samples, with the advantage of detecting genomes of noninfectious virus.<sup>20</sup> The time to perform RT-PCR is longer but the cost may be lower than for commercial rapid antigen detection kits, especially in developing countries. Real-time RT-PCR has enabled the development of assays that provide rapid quantitative detection of influenza A and B with high sensitivity.<sup>34,35</sup> These assays have great potential to replace other methods, because they are simultaneously rapid, highly sensitive, quantitative, and amenable to being used in multiplex format, which might include probes for several different respiratory pathogens.<sup>35</sup> However, the costs are still prohibitive for most laboratories in developing nations. Serologic diagnosis of influenza using paired acute and convalescent serum can be done retrospectively by a variety of techniques but mainly for serologic survey purposes.<sup>20</sup>

## TREATMENT

Amantadine and rimantadine are M2 ion channel blockers that inhibit influenza A virus replication at the uncoating step.<sup>20</sup> In uncomplicated influenza A in adults without underlying diseases, treatment with either drug can reduce the duration of influenza illness by approximately 1 to 2 days if started early, within 48 hours from the onset of symptoms. Amantadine is excreted in an unchanged state in the urine, while rimantadine is extensively metabolized after absorption and less than 10% of the dose is excreted unchanged in the urine. Elderly persons need only half the dose to achieve similar plasma levels. Amantadine or rimantadine may cause gastrointestinal upset and central nervous system side effects. Central nervous system (CNS) intolerance is more common with amantadine and, when severe, can be manifested as agitation, psychosis, seizures, and coma. Mild complaints including insomnia, dizziness, anxiety, dry mouth, anorexia, and nausea are reversible upon discontinuation. Amantadine and rimantadine are marketed as 100-mg tablets and 10-mg/mL syrup. The recommended dose is 100 mg twice daily for adults older than 65 years of age (100 mg/day for patients  $\geq 65$  years of age). For children under age 10 years, a rimantadine dose of 5 mg/kg/day (maximum, 150 mg/day) has been suggested.<sup>20</sup> Dose reductions proportional to the creatinine clearance (ClCr) are suggested for patients with renal insufficiency (amantadine for ClCr  $<60$  to 80 mL/min/1.73 m<sup>2</sup>; rimantadine for ClCr  $<10$  to 20 mL/min/1.73 m<sup>2</sup>). Influenza virus resistant to amantadine-rimantadine emerges in approximately one third of treated patients; such viruses are transmissible to close contacts and cause typical influenza illness. Resistance to these drugs renders them ineffective and is

sometimes present naturally, including in recent human isolates of H5N1 virus.<sup>20</sup>

The neuraminidase inhibitors zanamivir and oseltamivir inhibit both influenza A and B viruses by blocking the active site of the enzyme for cleavage of sialic acid, thus inhibiting virus release from infected cells and spread within the respiratory tract.<sup>36</sup> In adults and children older than 5 years, inhaled zanamivir (10 mg twice daily for 5 days) provides 1- to 2.5-day reduction in illness<sup>37</sup> and reduces antibiotic use for lower respiratory complications by 40%. Zanamivir is generally well tolerated but may uncommonly induce bronchospasm, particularly in those with influenza and pre-existing airway disease.<sup>20</sup> Oseltamivir (75 mg orally twice daily for 5 days) reduces illness severity, time to resumption of daily activities by 1 to 3 days, and rates of complications leading to antibiotic prescription and hospitalization by about 50% in adults. In children 1 to 12 years of age, oseltamivir reduces the frequency of otitis media and, consequently, antibiotic prescriptions. Side effects include mild-to-moderate nausea or emesis. Dosage of neuraminidase inhibitors does not need to be adjusted for the elderly.<sup>20</sup> Resistance emergence is uncommon with both drugs,<sup>20</sup> although a recent study of children treated with oseltamivir detected drug-resistant viruses in 18%, often in association with prolonged viral excretion, and showed that children can be a source of viral transmission, even after 5 days of treatment.<sup>38</sup>

Antipyretic-analgesic drugs may be used for influenza-induced fever and aches. Aspirin should be avoided because of its association with Reye's syndrome.

## PREVENTION AND CONTROL

Immunization with formalin-inactivated or live-attenuated multivalent influenza virus vaccines and chemoprophylaxis for influenza virus A are the methods available for preventing influenza. Influenza vaccine is used prior to the influenza season and currently includes one strain of influenza B and two strains of subtypes H3N2 and H1N1 of influenza A virus, chosen by the World Health Organization (WHO) surveillance network among the viruses most likely to circulate in the next influenza season.<sup>20,39</sup> The inactivated vaccine has an approximate 70% to 90% efficacy in preventing illness in healthy children and adults.<sup>39</sup> It also reduces influenza-related hospitalizations and mortality in elderly and high-risk patients. The Centers for Disease Control and Prevention (CDC) recommends the immunization of persons aged 50 years and older; residents of nursing homes; children and adults with chronic cardiovascular or pulmonary disease, including asthma; persons chronically ill with diabetes mellitus, renal dysfunction, or hemoglobinopathies; immunosuppressed patients including those with HIV infection; children and adolescents on chronic aspirin therapy who may develop postinfluenza Reye's syndrome; women who will be pregnant during the influenza season; children aged 6 to 23 months; those who can transmit influenza to persons at high risk, such as health-care workers and household contacts of those at high risk including children 0 to 23 months of age; crew members of cruise ships; providers of essential services; and unimmunized travelers to areas where influenza may be circulating, including the tropics, the southern hemisphere between April and September, and those traveling in large

organized tourist groups. In addition, vaccine is made available to anyone interested in reducing the likelihood of becoming ill with influenza.<sup>20,39</sup> The inactivated vaccine, administered as a single intramuscular (IM) dose shortly before influenza season (two doses in previously unimmunized children <9 years of age), is safe during pregnancy but should be avoided in persons with history of anaphylactic reactions to eggs.<sup>39</sup> Vaccine safety and efficacy in children has been extensively evaluated and has shown a favorable safety profile with efficacy in 1- to 15-year-old children of 77% to 91%. Inactivated vaccine is not currently recommended for children younger than 6 months, but vaccination of household contacts and caregivers should reduce the risk of these high-risk children contracting influenza. Healthy people aged 5 to 49 years who are not contacts of immunosuppressed patients can receive either inactivated or intranasal live-attenuated vaccines.<sup>39</sup>

Influenza inactivated vaccine has been recently introduced in many tropical areas of the world, with a composition based on influenza viruses circulating in the southern hemisphere. The vaccine is given prior to the influenza season, which for most countries in the southern hemisphere is between May and July.<sup>40</sup> In South America, annual vaccination of the elderly has reduced hospitalizations and mortality for respiratory diseases.<sup>41</sup> Continuous surveillance has already shown that regional variations of circulating influenza virus strains should be taken in consideration in the formulation of influenza vaccines with compositions more appropriate for South America.<sup>42</sup>

Live-attenuated, cold-adapted vaccines administered intranasally are well tolerated, genetically stable, and rarely transmissible and have the advantage of inducing local secretory immunoglobulin A (IgA) responses. Because of potential interference between components, two doses may be required in young children.<sup>20</sup> This vaccine was licensed in the United States in 2003, where it has become an option for healthy persons aged 5 to 49 years, including those in close contact with groups at high risk and those wanting to avoid influenza.<sup>39</sup> This vaccine is not recommended for persons with asthma and other chronic disorders of the pulmonary or cardiovascular systems; persons with underlying medical conditions, including diabetes, renal dysfunction, and hemoglobinopathies; persons with known or suspected immunodeficiency diseases or who are receiving immunosuppressive therapies; children or adolescents receiving aspirin or other salicylates; persons with a history of Guillain-Barré syndrome; pregnant women; and persons with a history of hypersensitivity to eggs.<sup>39</sup> Cold-adapted trivalent influenza vaccine is highly effective (92% in phase 3 studies) in preventing culture-confirmed influenza in healthy children and has provided protection against drift variant strains in some studies. In young and middle-aged adults, efficacy is generally comparable to that of inactivated vaccine.<sup>39</sup>

Other investigational approaches have been explored in influenza vaccine development, including recombinant HA produced in insect cells, virosomes incorporating surface glycoproteins, M2 protein conjugated with hepatitis B virus core, and naked DNA encoding influenza virus nucleoprotein or HA.<sup>20</sup> Cell culture-based vaccines (MDCK, Vero) have been approved in Europe and may offer an alternative to the limitations of the current egg-grown vaccines. The technique of

reverse genetics has been used to rapidly produce candidate vaccines against potential pandemic threat viruses.

Amantadine and rimantadine are approved for use, and are 70% to 90% effective in the prophylaxis of influenza A during outbreaks. Unvaccinated elderly persons, immunodeficient patients, patients in chronic care institutions experiencing outbreaks, persons who could not be vaccinated, and those who received a vaccine strain different from the outbreak strain may receive prophylaxis with amantadine or rimantadine. Prophylaxis should be started as early as possible at doses equivalent to those used for therapy, and continued until 1 week after the end of the outbreak for a total of at least 2 weeks.<sup>39</sup> Amantadine- and rimantadine-resistant mutants of influenza A virus occur in up to 30% of treated patients and may be associated with failure of drug prophylaxis.<sup>43</sup> Both oseltamivir (75 mg twice daily) and inhaled zanamivir (10 mg/dose twice daily) are more than 80% effective in the prophylaxis of influenza during outbreaks, but only oseltamivir has been approved for this indication in the United States.<sup>20,39</sup>

Antiviral agents, especially the neuraminidase inhibitors, could significantly help in the control of a future influenza pandemic by reducing lower respiratory complications and hospitalizations as well as potentially person-to-person transmission. However, supply limitations<sup>44</sup> pose a real difficulty. Therefore, policies to ensure a reasonable supply of these drugs, as well as directions to optimize the use of limited supplies, are important issues to be considered.<sup>18</sup>

## ■ Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is the single most important viral cause of lower respiratory disease and a major cause of morbidity and mortality in children worldwide. RSV is the leading cause of hospitalization in young children in developed and developing countries.<sup>45</sup> In tropical areas, RSV has been the most frequently isolated virus in hospital-based ARI studies of children.<sup>5</sup>

### AGENT

RSV, the only known human pathogen of the genus *Pneumovirus* in the family Paramyxoviridae, is a pleomorphic RNA virus with helical nucleocapsid and lipid-containing envelope. Antigenic differences in the surface glycoprotein G permit the classification of RSV into groups A and B, each with antigenic subgroups.<sup>46</sup> The interaction of RSV envelope glycoprotein G with glycosaminoglycans enables adherence to the cell surface. However, G protein-independent mechanisms of attachment must exist, since mutants devoid of G protein can also enter host cells. RSV enters the cell by fusion of viral envelope with cell membranes, a process mediated by binding of the viral F protein to the cell GTPase RhoA.<sup>46</sup> The syncytia resulting from fusion of the infected cells to adjacent ones are the major feature of the cytopathic effect of paramyxoviruses. Once in the cytoplasm, the negative-strand RNA is transcribed by viral transcriptase into mRNAs, which then direct viral protein synthesis. An intermediate positive-strand full-length cRNA serves as a template for the synthesis of progeny negative-strand RNA. As they bud through the

cell membrane, the virions acquire a glycoprotein-containing envelope.<sup>46</sup> RSV causes asymptomatic infection in a variety of experimental animals, but natural infection occurs only in humans and chimpanzees.<sup>47</sup> RSV grows well in several human heteroploid cell lines, such as HEp-2, HeLa, and A549, and is sensitive to ether, chloroform, detergents, and a pH less than 5. RSV is inactivated at 55°C, survives poorly on porous surfaces, and loses infectivity significantly by slow freezing and storage at temperatures above 4°C.<sup>46</sup>

## EPIDEMIOLOGY

RSV occurs worldwide and causes annual outbreaks in temperate climates in the winter and early spring, with sporadic cases throughout the year.<sup>47</sup> In tropical regions, where temperature fluctuations are smaller and the only significant seasonal variable is often rainfall, RSV outbreaks tend to occur in the rainy seasons. Such has been the case in Malaysia, Hong Kong, India, Papua New Guinea, Colombia, Kenya, and The Gambia.<sup>12</sup> Interestingly, in Singapore RSV peak activity occurs from March to August, a period of higher temperature, higher day-to-day temperature variation, and lower relative humidity.<sup>48</sup> In southeast Brazil, RSV occurs seasonally, within a broader range of months from February through July, after the rainy season and when temperatures tend to be cooler, with slight variations from year to year.<sup>49</sup> In regions where average winter temperatures are colder, such as in São Paulo city and the southernmost parts of Brazil, as well as in Argentina, RSV peak activity tends to occur in July and August.<sup>50–52</sup>

Most children have specific serum RSV antibody by age 2 years, but reinfections occur throughout life. More than one subtype of either RSV group may cocirculate in one season, with group predominance changing from year to year, without apparent correlation with clinical or epidemiologic characteristics of the illness they cause.<sup>49,53</sup> RSV transmission requires close contact and occurs either by large-particle aerosols or by contamination of hands and inoculation into the eye or nose. Secondary infections in family contacts of an index case are common, after an average incubation period ranging from 2 to 8 days.<sup>45</sup>

It is estimated that 30% of all infants will have RSV infection that requires medical attention and that 2% of them will be hospitalized.<sup>45</sup> An estimated 10% of children will have bronchiolitis in their first year of life, with 60% to 90% of those infections caused by RSV.<sup>54</sup> In southeast Brazil, RSV is the leading cause of lower respiratory tract infections in children younger than 1 year of age and is responsible for up to 85% of hospitalizations in this age group during peak months.<sup>52</sup>

## CLINICAL FEATURES

The spectrum of illnesses caused by RSV ranges from mild URI to severe LRI, including pneumonia, bronchiolitis, tracheobronchitis, and croup.<sup>45</sup> In infants and young children, URI with fever and otitis media is common. During outbreaks, RSV RNA has been detected in up to 75% of middle ear effusions in children with RSV infection and acute otitis media.<sup>55</sup>

The most frequent LRI caused by RSV in infants is bronchiolitis, usually preceded by 2 to 3 days of URI symptoms, and progressing to lower respiratory tract involvement

characterized by tachypnea, dyspnea, cough, expiratory wheezing, air trapping, and in more severe cases, intercostal muscle retractions and cyanosis. Fever is present in only 50% of infants. Chest radiographs may show hyperaeration of the lungs and sometimes segmented atelectasis.<sup>45</sup> Blood counts usually show lymphocytosis, and an increase in neutrophils with a left shift could be associated with bacterial superinfection. The most frequent bacterial superinfection in children with RSV infections is acute otitis media, which may be found in up to 60% of children with bronchiolitis.<sup>56</sup> However, more serious bacterial infections that may require sepsis work-up is uncommon in previously healthy infants with RSV infections.<sup>57</sup> This may be different, however, in developing tropical areas, where RSV frequently causes infections in children previously debilitated by other diseases and malnutrition.

Infants with congenital heart disease, premature infants, or infants with underlying pulmonary conditions, such as cystic fibrosis and bronchopulmonary dysplasia, as well as immunocompromised hosts of any age, are at risk for severe and fatal RSV infections. HIV-infected children with RSV infections have a higher rate of pneumonia and prolonged illness and virus shedding, but the general severity of the RSV disease is not increased.<sup>45</sup> Differential diagnosis of acute bronchiolitis includes asthma, pneumonia, congenital heart and lung diseases, and cystic fibrosis. Particular clinical signs are generally not accurate predictors of specific viral causes, but in a study conducted in the Philippines, wheezing was a significant predictor of viral LRI, while manifestations of higher severity, such as chest indrawing and cyanosis, were more often associated with bacterial LRI.<sup>58</sup> The most frequent RSV illness in children over 3 years of age and adults is URI with coryza and cough, sore throat, and hoarseness, often accompanied by low-grade fever. Exacerbations of chronic pulmonary diseases and wheezing can also be seen in adults with RSV infection.<sup>45</sup>

The role of RSV infections in causing wheezing and asthma exacerbations in infants is well established in studies conducted in temperate areas.<sup>59</sup> Similar observations have been made in an emergency room study conducted in Southeast Brazil, which found that infection with respiratory viruses, especially RSV, and a family history of allergy were independently associated with wheezing.<sup>60</sup> Similar findings have been observed in urban Nigerian preschool children.<sup>61</sup>

RSV has been increasingly recognized as a cause of LRI in the elderly, mainly characterized by interstitial pneumonia, prolonged cough, and dyspnea in persons with chronic pulmonary conditions, and it should be considered in the differential diagnosis of flulike illnesses.<sup>62</sup>

## PATHOGENESIS AND IMMUNITY

RSV replicates in respiratory epithelium to reach titers as high as 10<sup>6</sup> TCID<sub>50</sub>/mL in nasal secretions of infected babies, and virus shedding may be as prolonged as 3 weeks after the symptoms disappear.<sup>46</sup> RSV spreads from cell to cell and may involve the entire respiratory tree, reaching bronchioles in 1 to 3 days after the onset of rhinorrhea. Replication in the bronchiolar epithelium causes necrosis of ciliated cells, syncytia formation, peribronchiolar inflammation with abundant lymphocytes and macrophages, and impairment of secretion clearance, resulting in small airway obstruction and the

hyperinflation characteristic of bronchiolitis. Pneumonia frequently coexists, evidenced by interstitial mononuclear infiltrate, eosinophilic cytoplasmic inclusions in epithelial cells, and multinucleated giant cells. The most severe RSV disease occurs in young babies, whose immature airways may be unable to compensate for the pathologic changes.<sup>46</sup>

Naturally acquired immunity to RSV is incomplete and short-lived, but the severity of illness tends to decrease with reinfections. Local secretory IgA correlates better with protection than does serum antibody level and age, and pre-existing virus-specific maternal antibodies influence the development of neutralizing antibodies. Cell-mediated immune response is central to recovery from RSV infection, and patients with suppressed cell-mediated immune response are at risk of severe RSV pulmonary disease and fatal outcome.<sup>45,46</sup>

The type of immune response to the virus is probably a major factor in the development of wheezing and asthma exacerbations. A bias toward a Th2 cytokine response seems to be associated with more severe disease, whereas a Th1 response leads to effective viral clearance and milder illness. The virus itself generally triggers a Th1 response, but a pre-existing Th1 deficiency may be associated with disease severity in some children. It has been suggested that RSV bronchiolitis may be a marker of predisposition to wheezing or asthma later in life.<sup>46,63</sup>

Children vaccinated with a formalin-inactivated RSV vaccine developed in the 1960s had severe disease when exposed to natural infection, apparently as a consequence of an imbalance between protective and immunopathologic T-cell responses elicited by previous parenteral immunization with inactivated RSV. This would favor a CD4+ Th2 cytokine pattern in response to subsequent RSV infections, whereas a previous natural infection would favor a CD4+ Th1 pattern in response to reinfection.<sup>64</sup>

## DIAGNOSIS

Nasopharyngeal aspirates or swabs, nasal washings, and lower respiratory samples are all appropriate specimens for RSV isolation. This is usually accomplished in cultures of HEp-2 cell line, in which RSV induces syncytia in 3 to 5 days. RSV antigen detection by EIA, including membrane-based EIA, is sensitive and specific and requires virtually no equipment, making it ideal for field studies. Rapid RSV detection by IF of exfoliated respiratory cells may be even more sensitive than EIA-based methods.<sup>45,46</sup>

The increasing use of rapid tests has facilitated the assessment of RSV in tropical areas.<sup>1</sup> Ideally, a combination of a rapid method with viral isolation should be used for maximal RSV detection, but the cost may still be prohibitive for the meager resources available in some tropical areas. Detection of RSV RNA by conventional RT-PCR has shown suboptimal sensitivity, especially when compared with easy-to-perform, more sensitive rapid methods.<sup>45</sup> However, more recently developed assays based on real-time RT-PCR are proving to be more sensitive than conventional RT-PCR assays, with the added conveniences of being rapid, quantitative, and amenable to simultaneous detection and subtyping of RSV directly from clinical specimens.<sup>65</sup> RSV serology has limited value for case management but may be useful for epidemiologic surveys.<sup>45</sup>

## TREATMENT

URI caused by RSV requires no specific treatment, and antibiotics are needed only when bacterial otitis media or sinusitis are present.<sup>45</sup> The supportive treatment of infants with RSV bronchiolitis consists basically in preventing hypoxemia and electrolyte imbalance, in addition to aerosolized bronchodilators. The lack of obvious correlation between radiologic findings and disease severity suggests that a chest film should be recommended only for severely ill or deteriorating infants.<sup>54</sup> To prevent hypoxemia, requirements may vary from simple removal of respiratory secretions and proper positioning of the infant to mechanical respiratory assistance and even extracorporeal membrane oxygenation (ECMO). Pulse oximetry has been advocated to assess oxygen needs, but in tropical developing areas, where oximeters may not be available, serial clinical assessment is essential to monitor disease progression. For this purpose, crackles and cyanosis seem to correlate better with hypoxemia than tachypnea and intercostal retraction.<sup>54</sup> Correction of hypoxemia can be accomplished with 40% or lower oxygen concentrations.<sup>45</sup> Oxygen should be humidified with saline and delivered by mask if head boxes or tents are unavailable. The role of corticosteroids remains unclear with some evidence that they are not beneficial.<sup>54</sup>

The only antiviral drug currently approved for the treatment of infants with RSV is the synthetic nucleoside ribavirin, delivered by small-particle aerosol via a mist tent, mask, oxygen hood, or ventilator. It is recommended only for infants and young children with an underlying condition, such as congenital heart disease, cystic fibrosis, or immunosuppression. Premature infants, infants younger than 6 weeks of age, and severely ill infants may also be considered for therapy.<sup>66</sup> Aerosolized ribavirin is well tolerated, but it is expensive and its prolonged administration requires facilities that may not be available in impoverished tropical areas. Passive immunotherapy with RSV immunoglobulin, in combination with aerosolized ribavirin, improved the outcome of RSV pneumonia in bone marrow transplant patients.<sup>67</sup> The use of RSV-intravenous immunoglobulin (IVIG) or humanized monoclonal antibody against RSV has shown no benefit for the treatment of RSV infections in infants.<sup>45</sup>

## PREVENTION AND CONTROL

No vaccine is currently available for RSV prophylaxis. The disease enhancement caused by formalin-inactivated vaccine in the 1960s plus results of more recent unsuccessful trials of live-attenuated vaccines, have significantly slowed progress toward an RSV vaccine.<sup>2</sup> Purified fusion protein vaccine has been tested for safety and immunogenicity in seropositive children older than 18 months, and was associated with reduction of lower respiratory tract illness, but not of RSV infection rates, in children with cystic fibrosis.<sup>45</sup> These and other candidate subunit vaccines, as well as intranasal live-attenuated vaccines, should be tested in high-risk children with underlying bronchopulmonary diseases.

Passive immunization of high-risk infants with monthly infusions of RSV immunoglobulin during the RSV season reduced the incidence and severity of RSV infections in high-risk children.<sup>68</sup> This costly intervention is the only available

means of protecting high-risk children against serious RSV LRI. Monthly intramuscular injections of humanized monoclonal antibody should be considered for passive immunoprophylaxis during RSV season for high-risk infants such as preterm infants less than 6 months old, children with congenital heart disease, and children less than 2 years of age with bronchopulmonary dysplasia.<sup>45</sup>

Hospitalized infants with RSV infection should be isolated or grouped to prevent cross-infection. Hand washing; use of eye-nose goggles, gowns, and gloves; and decontamination of surfaces and fomites are additional nosocomial infection control measures.<sup>45</sup>

## ■ Human Parainfluenza Viruses

Human parainfluenza viruses (HPIVs) are the single most frequent cause of croup in infants and children worldwide and are second only to RSV as cause of LRI in infants.<sup>45,69</sup> Little is known about the epidemiology of HPIVs in tropical countries, but these viruses have been detected in up to 13% of children in hospital-based ARI studies in developing countries.<sup>5,21</sup>

### AGENTS

HPIVs are distributed in two genera of the family Paramyxoviridae, sharing the structural and biological characteristics already mentioned in the RSV section. HPIVs are classified antigenically into types 1 to 4, and HPIV-4 has subtypes A and B. HPIV types 1 and 3 are classified in the genus *Respirovirus*, while HPIV types 2 and 4 are in the genus *Rubulavirus*. HPIV-1 and -3 are the types most frequently associated with LRI in children, the immunocompromised, the chronically ill, and the elderly, whereas PIV-4 causes mostly URI in both children and adults.<sup>69</sup>

Binding of HPIV to sialic acid in the cell membrane is mediated by the glycoprotein HN, which contains hemagglutinin and neuraminidase activities. Fusion of viral and cell membranes is mediated by the viral F protein, which is cleaved by cellular proteolytic enzymes.<sup>45</sup> Once inside the cell, the cycle is similar to other Paramyxoviridae, as summarized in the RSV section. HPIVs can be propagated in primary simian or human kidney cells and in several cell lines, such as HEp-2, Vero, MDCK, LLC-MK2, BHK, and HeLa.<sup>69</sup> A variety of experimental animals undergo asymptomatic infection with PIV, but only higher primates develop symptoms.<sup>45,69</sup>

### EPIDEMIOLOGY

Primary HPIV infection occurs early in childhood, and by age 5 virtually all children are seropositive.<sup>19</sup> An estimated one third of all viral LRIs in children in the United States are caused by HPIV-1 and -3.<sup>69,70</sup>

In most temperate regions, HPIV-1 and -2 cause epidemics in the fall of alternate years, either in co-circulation or alternating with one another. The biennial pattern of HPIV-1 is found in both hemispheres.<sup>69</sup> HPIV-1 causes most croup epidemics, whereas HPIV-2 more frequently causes illness with milder manifestations, although it can also cause croup.<sup>69</sup> HPIV-3 occurs endemically throughout the year, with sporadic spring outbreaks mainly among infants, and HPIV-4 occurs

sporadically throughout the year in children and adults.<sup>45,69,70</sup> In tropical areas HPIVs may account for up to 15% of child hospital admissions due to LRI.<sup>21</sup> Community-based ARI studies in children under age 5 years show higher HPIV activity during rainy seasons in tropical countries.<sup>3,24</sup> HPIVs were the most frequent viruses detected in school-aged children with bronchial asthma exacerbations in urban Nigeria.<sup>61</sup>

HPIVs spread mainly within families and closed communities, such as nurseries, day-care centers, and pediatric wards, with high secondary attack rates. In a longitudinal study conducted with children less than 2 years of age with ARI in a day-care center for low-income families in Northeast Brazil, HPIVs represented 11% of the viruses detected.<sup>11</sup>

The virus does not persist long in the environment and is transmitted mainly by large droplets and fomites.<sup>45</sup> Viral shedding usually lasts 3 to 10 days, but shedding of HPIV for months has been reported in very young children and immunosuppressed hosts.<sup>71</sup>

### CLINICAL FEATURES

Primary HPIV infection may cause rhinitis, pharyngitis, laryngotracheobronchitis (croup), bronchiolitis, or pneumonia. Approximately two thirds of all PIV infections in children result in febrile URI with associated otitis media in 10% to 34%. The remaining one third of PIV infections are cases of croup, bronchiolitis, or pneumonia.<sup>61,63</sup> HPIVs, mainly of types 1 and 2, cause up to 74% of all cases of croup.<sup>69</sup>

Croup is the most striking clinical presentation of HPIV infection and is most common between the ages of 6 and 36 months.<sup>72</sup> Croup is manifested by inspiratory stridor, barking cough, and hoarseness caused by subglottic edema, preceded by rhinorrhea, mild cough, and low-grade fever.<sup>45,72</sup> Most children recover in 2 to 5 days, but some may develop bronchiolitis and pneumonia and present with a bronchopneumonia-croup syndrome.<sup>45,69,72</sup>

Since immunity to HPIVs is incomplete, infections tend to occur throughout life, but little is known about HPIV infections in adults. In general, adults have only nonspecific URI, commonly with hoarseness.<sup>45</sup>

HPIVs can cause particularly severe diseases in immunocompromised hosts, especially children with severe combined immunodeficiency and bone marrow transplant patients. Mortality in bone marrow transplant patients with HPIV infection varies from 10% to 20% in most series.<sup>45,69</sup>

### PATHOGENESIS AND IMMUNITY

HPIVs replicate in ciliated epithelial cells, causing cytolysis of the respiratory mucosa. The infection begins in the upper respiratory tract and tends to disseminate down the respiratory tree. The larynx and trachea are mostly involved in the croup syndrome, and extensive involvement of the lower respiratory tree may be present in tracheobronchitis, bronchopneumonia, and bronchiolitis.<sup>69,71,72</sup>

Similar to influenza, factors determining the extent of HPIV infection include the susceptibility of the viral F protein to be cleaved and tissue-specific differences in the production of proteases to cleave it.<sup>45</sup>

Host immunity is largely mediated by humoral immunity to the two surface proteins HN and F. Virtually all children by

the age of 3 years will have seroconverted to HPIVs, generally first to HPIV-3 but later also to HPIV-1 and -2. At school age, a significant proportion of children will have seroconverted also to HPIV-4. Secretory antibody targeted to the HN glycoprotein is the best marker of protection against PIV,<sup>71</sup> but the protection conferred by antibodies is limited, and repeated infections will develop. T-cell immune response seems to be involved in the clearance of virus and additionally in the development of inflammatory infiltrate, edema, and excess mucus secretion,<sup>69</sup> and immunocompromised hosts may develop progressive and even lethal disease.<sup>73</sup>

Like RSV, PIVs cause mononuclear interstitial infiltrate, epithelial necrosis, inflammatory exudate into the alveoli, and hyaline membrane formation in the lungs.<sup>45</sup>

## DIAGNOSIS

PIV is present in respiratory secretions until about 8 days from the onset of symptoms and can be isolated in monkey kidney primary cells and several continuous cell lines. Virus can be detected in the monolayers by hemadsorption with guinea pig erythrocytes in around 3 days after inoculation and confirmed by IF.<sup>69,71</sup> Shell-vial assays have been developed for HPIV detection but with mixed results.<sup>69</sup> IF of exfoliated respiratory epithelial cells has produced conflicting and sometimes disappointing results, with most studies reporting sensitivities between 50% and 75% at best.<sup>69</sup> Detection of viral RNA by RT-PCR, including commercially available multiplex assays for several respiratory viruses, has enhanced the sensitivity of detection of HPIV from clinical samples.<sup>69,74</sup> Real-time PCR for respiratory viruses in multiplex format is sensitive and specific for HPIV.<sup>35</sup>

## TREATMENT

At present, only supportive and symptomatic treatment is available for PIV infections. Management of croup includes supplemental oxygen and racemic epinephrine nebulization in hospitalized patients. Mist therapy, although traditional, has no proven value.<sup>72</sup> Short-term, high-dose systemic corticosteroids may reduce the need for intubation, and nebulized budesonide has a rapid effect and is as safe and efficacious as nebulized epinephrine in moderately severe croup.<sup>72</sup> Several antiviral agents have in vitro activity against HPIVs, but none has reached clinical testing.<sup>69</sup> There have been anecdotal reports of reduced HPIV shedding in immunocompromised patients treated with ribavirin, but this finding has not resisted scrutiny.<sup>69</sup> Future possibilities include the BCX 2798 and BCX 2855 compounds, whose design is based on the three-dimensional structure of the HN protein, which inhibit the hemagglutinin and neuraminidase activities of the protein and were effective in vitro and in an animal model against HPIV-1, -2 and -3.<sup>75</sup>

## PREVENTION AND CONTROL

No interventions are available for the prevention of HPIV infections. Early trials with inactivated HPIV vaccine in the 1960s were unsuccessful.<sup>69</sup> Recently, a live-attenuated, cold-adapted HPIV-3 vaccine was found to be immunogenic for children as young as 1 month of age and holds promise for

further development.<sup>69</sup> The same vaccine was tested in combination with a live-attenuated RSV vaccine candidate, showing that this approach is feasible and deserves further study.<sup>76</sup> Characterization of HPIV proteins HN and F has led to development of subunit immunogens that showed efficacy in animal models.<sup>69</sup>

## Rhinoviruses

Human rhinoviruses (HRVs) are the most frequent respiratory pathogens of humans.<sup>77</sup> They were the most frequently isolated viruses in children under 5 years of age with ARI in an urban slum in northeast Brazil.<sup>3</sup>

## AGENTS

Human rhinoviruses are small, nonenveloped, positive-strand RNA viruses in the family Picornaviridae, with over 100 identified serotypes.<sup>77</sup>

HRV serotypes have been classified according to receptor-specificity into three groups. The major group includes 91 serotypes whose receptor is intercellular adhesion molecule-1 (ICAM-1); the minor group contains 10 serotypes whose receptor is the low-density lipoprotein receptor (LDLR); and the remaining serotype, HRV-87, utilizes a sialoprotein as cell receptor. Unlike other picornaviruses, HRVs are acid-labile, a property that distinguishes them from enteroviruses.<sup>77</sup>

The HRV genome is a monocistronic single-stranded RNA, packed in an icosahedral capsid composed of 12 pentamers. Surrounding the fivefold vertex, each pentamer contains a 1.2- to 3.0-nm-wide canyon that contains the receptor binding site. Following receptor binding, the viral positive-strand RNA is released into the cytoplasm and directs the synthesis of a polyprotein, whose cleavage products include an RNA polymerase. This enzyme will produce an expanding pool of positive-strand RNA using as a template an intermediate negative-strand RNA. The positive-strand RNA can be either translated into virion proteins or packaged as a genome into newly assembled virions. The HRV replication cycle takes place in the cytoplasm, and mature virions are released when the host cell is lysed.<sup>77</sup>

HRVs are resistant to ethanol, ether, chloroform, and non-ionic detergent but are sensitive to UV light; to pH lower than 5 and higher than 9; and to halogens such as chlorine, bromine, iodine, and phenolic disinfectants. They are stable for days on environmental surfaces and for years at minus 70°C.<sup>77</sup>

HRV infects only higher primates and causes illness only in humans. Several cell lines of primate origin support HRV propagation, but certain strains of HeLa cells and human embryonic fibroblasts provide higher sensitivity for HRV isolation from clinical specimens.<sup>78</sup> The optimal growth temperature for HRV is 33°C to 35°C.<sup>77</sup>

## EPIDEMIOLOGY

HRV infections occur in people from all continents, including remotely located population groups, such as Bushmen from the Kalahari Desert, native Alaskans, and an isolated Amazon Indian tribe.<sup>79</sup> HRV has been estimated to

cause up to 80% of all autumn colds in temperate climates.<sup>80</sup> In tropical countries, very few community-based studies of viral ARI have used adequate HRV detection methods,<sup>5</sup> and this has limited the assessment of the actual impact of HRV in those areas. However, available evidence indicates that HRV is frequently associated with ARI in children in Brazil. In Fortaleza, a city in northeast Brazil, HRV detected by isolation in cell culture represented 46% of the viruses in children under 5 years of age with ARI.<sup>3</sup> In Salvador, another city in the same region, HRV represented 52% of the viruses detected by RT-PCR in association with ARI in children younger than 2 years of age attending a day-care center for the underprivileged.<sup>11</sup> Data on the frequency of HRV among adults in tropical countries are even more scarce. In Singapore, HRV was detected in 20% of the samples obtained from adults with ARI symptoms attending primary care centers.<sup>81</sup>

HRV transmission requires close exposure and occurs mainly by hand-to-hand contact, followed by self-inoculation into the eye or nose, but also by airborne spread. Once HRV reaches the nasal cavity, infection occurs in virtually 100% of susceptible subjects, and approximately 75% of those infected develop illness after a 1- to 2-day incubation.<sup>77</sup> Children play a central role in spreading the virus in the household.

Evidence suggests that indoor HRV transmission is favored by high relative humidity and crowding of young children, as occurs in the United States at the beginning of the school term, which may explain the autumn seasonal peak of HRV.<sup>77</sup> In tropical northeastern Brazil, however, where relative humidity remains above 70% reaching 90% during the rainy season, longitudinal studies have found no obvious HRV seasonality.<sup>3,11</sup>

## CLINICAL FEATURES

HRV colds are indistinguishable from colds of other viral causes and consist of nasal discharge, nasal obstruction, sneezing, sore or scratchy throat, hoarseness, cough, and headache. Facial and ear pressure may be present. Fever and malaise are uncommon. These symptoms last approximately 7 days but may persist for up to 2 weeks in 25% of cases. Infants and toddlers may display only nasal discharge and be otherwise asymptomatic.<sup>77</sup> The majority of patients have obstruction and mucosal abnormalities of the sinus cavities, eustachian tubes, and middle ear, which predispose to secondary bacterial sinusitis and otitis media, each complication found in approximately 2% of all colds.<sup>82</sup> HRV RNA may be detected by RT-PCR in maxillary sinus brushings in 40% of adults presenting with acute sinusitis,<sup>83</sup> and in 24% of the samples of middle ear fluid from children less than 7 years of age with diagnosis of acute otitis media.<sup>84</sup>

HRV is frequently associated with exacerbations of chronic obstructive pulmonary disease and asthma attacks in children over 2 years of age and in adults.<sup>59,77,85</sup>

## PATHOGENESIS AND IMMUNITY

HRV replication is restricted to the respiratory epithelium, taking place in scattered ciliated cells of the nose and in non-ciliated cells of the nasopharynx.<sup>86</sup> This tropism seems to be a consequence of receptor availability. Infection of a limited number of cells triggers the release of cytokines, chemokines,

and inflammatory mediators, which together with stimulation of the local parasympathetic nerve endings, results in the cold symptoms. Kinins, prostaglandins, and proinflammatory cytokines and chemokines may contribute to vasodilation, increased vascular permeability, influx of polymorphonuclear leukocytes, exocrine gland secretion, and nerve ending stimulation, resulting in nasal obstruction, rhinorrhea, sneezing, cough, and sore throat.<sup>77</sup>

Serotype-specific neutralizing IgM, IgG, and IgA antibodies develop in most infected persons in 7 to 21 days and persist for years. Protection from infection is partially attributed to the presence of IgA antibody in nasal secretions, and recovery from illness is more dependent on cell-mediated immunity. HRV-induced blastogenesis, natural killer cell activity, mitogen-stimulated cell production of IL-2 and IFN- $\gamma$  have been documented during HRV infection.<sup>77,87</sup> HRV induces the expression of human  $\beta$ -defensin 2 (HBD-2) in the respiratory epithelium, which supports a role for HBD-2 in host defense to HRV infection.<sup>88</sup>

## DIAGNOSIS

HRV can be detected in respiratory secretions by isolation in cultures of susceptible cell lines.<sup>78</sup> HRV shedding peaks around 48 hours after infection and declines rapidly, but may remain at low levels for up to 3 weeks.<sup>77</sup> Cultures should be kept at 33°C to 35°C in a roller drum and examined for 10 to 14 days. The presence of HRV, indicated by the typical CPE, is confirmed by the acid sensitivity of the isolate. Rapid immunocytochemical methods are not available because of the large number of serotypes. RT-PCR in clinical samples is more sensitive and less tedious than HRV isolation,<sup>83</sup> and the recently introduced real-time PCR-based assay is more sensitive than conventional RT-PCR.<sup>89</sup> PCR-based assays have been useful in studies to assess the impact of HRV in different settings. The homotypic nature of HRV antibodies restricts serology to experimental settings.<sup>77</sup>

## TREATMENT

Trials of antiviral agents for HRV have been conducted, but no specific treatment suitable for routine use has yet been identified, mainly because of lack of potency, untoward side effects, and drug delivery problems.<sup>90</sup> Rupintrivir, a selective inhibitor of HRV 3C protease, has potent, broad-spectrum anti-HRV activity in vitro. A double-blind, placebo-controlled clinical trial of intranasal rupintrivir in experimental HRV infection reduced symptoms by 33% and also decreased viral titers and nasal discharge.<sup>91</sup>

Symptomatic relief from cold symptoms can be obtained with a broad variety of nonprescription medications. Systemic sympathomimetic decongestants, such as pseudoephedrine, may reduce nasal obstruction, first-generation antihistamines may reduce sneezing and rhinorrhea, and nonsteroidal anti-inflammatory drugs such as naproxen or ibuprofen may reduce headache, cough, and systemic symptoms.<sup>77</sup>

## PREVENTION AND CONTROL

The large number of HRV serotypes with minimal cross-antigenicity has hampered the development of an HRV vaccine.

It may be possible to reduce exposure to HRV by hand washing after contact with a cold sufferer or after handling objects that may have been contaminated with respiratory secretions.<sup>77</sup> Studies in experimentally infected volunteers show that application of the virucidal agents salicylic acid or pyroglutamic acid to the hands reduced recovery of rhinovirus from the hand skin of treated persons as compared with controls.<sup>92</sup> This result suggests that rhinovirus transmission can be prevented by virucidal hand treatments.

Short-term, postexposure prophylaxis by intranasal IFN- $\alpha$  significantly reduced the incidence of HRV colds in household contacts of an index case.<sup>93</sup> However, the cost and difficulty of making the drug available to homes in a timely fashion reduce the utility of this approach for extended use by populations, especially in tropical countries.

Rupintrivir has also been evaluated for prophylaxis of HRV colds starting 6 hours prior to inoculation of human volunteers. This approach reduced the proportion of subjects with positive viral cultures and viral titers but did not affect the frequency of colds.<sup>91</sup>

## ■ Respiratory Adenoviruses

Respiratory infections caused by adenoviruses are among the most frequent illnesses that these viruses cause, particularly in children under age 5 years.<sup>94</sup> Adenoviruses have been frequently isolated in ARI studies in tropical countries.<sup>5</sup> In the south cone of South America, adenoviruses were the second most frequent virus recovered from children hospitalized for ARI.<sup>95</sup>

### AGENTS

Adenoviruses are nonenveloped, icosahedral DNA viruses of the genus *Mastadenovirus* in the family *Adenoviridae*.<sup>94</sup> Adenoviruses are distinguished antigenically by group-specific (A through F) and type-specific (1 through 49) antigens and by genomic subtypes identified by restriction site mapping.<sup>93,94</sup>

The adenovirus capsid consists of three morphologically, antigenically, and functionally distinct types of capsomers: hexons, penton bases, and fibers that project from the penton bases. The hexon and penton bases contain complement-fixing, group-specific antigens common to all human adenoviruses, whereas the fibers have primarily neutralizing and hemagglutination-inhibiting, type-specific antigens. Adenoviruses are commonly accompanied by small, single-stranded DNA parvoviruses known as adenoassociated viruses, which do not seem to cause any specific disease. Most people have antibodies to at least one of the four serotypes of adenoassociated virus by age 10 years.<sup>96</sup>

The fiber protein binds to the host cell, through the protein coxsackie and adenovirus receptor (CAR) of the immunoglobulin superfamily, which serves as a high-affinity receptor for adenoviruses. The class I major histocompatibility complex (MHC) also may serve as receptor for adenovirus 5.<sup>94</sup> Ligand-receptor interaction facilitates interaction of the penton base with cell surface integrins, which triggers entry. After endocytosis, the double-stranded linear genomic DNA is transported to the nucleus, where “early” and “late” sets of viral genes are transcribed, resulting in mRNAs coding for

structural and nonstructural proteins. Virus assembly takes place in the nucleus, and the infectious cycle is completed by the release of up to 1 million virions upon cell lysis.<sup>94</sup>

Adenoviruses replicate well in continuous cell lines of epithelial origin, such as HEp-2, HeLa, and A549, and can be adapted to grow in human embryonic lung fibroblasts. They are stable over a wide pH range (5 to 9), resistant to isopropyl alcohol, ether, and chloroform, stable for weeks at room temperature and for years at approximately 20°C or colder, and can be lyophilized. They are inactivated by sodium hypochlorite and a temperature of 60°C for 2 minutes.<sup>97</sup>

### EPIDEMIOLOGY

Respiratory transmission of adenoviruses occurs at all ages but is of prime importance during epidemics among military recruits. Ocular transmission has been associated with swimming pools and physician offices where sterilization or hand washing has been inadequate. Asymptomatic infection and a prolonged carrier state are common.<sup>94</sup>

Low-number adenovirus serotypes (1, 2, 3, and 5) are more frequent before age 5 years and account for 5% to 20% of cases of URI and approximately 5% of cases of LRI in children.<sup>98</sup> In adults, adenoviruses occur sporadically and cause mostly URI. Infections by adenoviruses types 4 and 7 are usually epidemic, with attack rates of 6% to 16% per week in newly assembled military recruits, whose adenovirus carriage rate may be as high as 18%.<sup>94</sup> In this group, the adenoviral syndromes vary from mild colds to severe LRI, but overall attack rates may reach 80%, with 20% to 40% of the individuals needing hospitalization.<sup>94</sup>

In temperate climates, adenoviral infections are more frequent in late winter, spring, and early summer, whereas in northeast Brazil they seem to occur year-round.<sup>5</sup> In Salvador, also in northeast Brazil, adenoviruses were detected in 11% of children younger than age 2 years with ARI in a day-care center.<sup>11</sup> In tropical areas the incidence of adenovirus infections in military recruits is lower, and different serotypes may be involved.<sup>98</sup>

Pharyngoconjunctival fever, commonly caused by adenoviruses types 3 and 7, may be epidemic or endemic among children during the summer in temperate climates. Inadequate chlorination or filtration of swimming pools and lakes has been associated with epidemics.<sup>99</sup> The incubation period of adenovirus infections averages 10 days.<sup>98</sup>

### CLINICAL FEATURES

Adenovirus respiratory diseases may involve all parts of the respiratory tract, and up to 50% of nonepidemic infections are asymptomatic. In fact, adenoviruses were discovered because of their propensity for latency in adenoidal tissue.<sup>94,98</sup> In southeast Brazil, adenoviruses were detected with equal frequency in wheezing young children and asymptomatic controls.<sup>60</sup>

Most adenoviral illnesses consist of febrile colds, and in children the fever may be high and long-lasting. Pharyngitis is common and may be associated with fever, pharyngeal exudate, granular appearance of the mucosa, and anterior cervical adenopathy, similarly to streptococcal pharyngitis.<sup>94</sup> Adenoviruses can be recovered from up to 20% of cases of

pharyngitis in small children. Pharyngitis may be concurrent with pharyngoconjunctival fever, a syndrome caused by adenovirus types 3 and 7 and characterized by conjunctivitis, frequently unilateral, which may last for 1 to 2 weeks, preauricular adenopathy, cough, rhinitis, malaise, and fever.<sup>99</sup> The most frequent complication of adenoviral colds is acute otitis media, which occurs in up to 30% of cases.<sup>100</sup>

Adenovirus LRIs consist mainly of bronchitis and pneumonia, and may make up over 10% of childhood LRIs in temperate areas.<sup>101</sup> Adenoviruses may cause permanent lung parenchymal damage, especially when concurrent with measles.<sup>101</sup> Epidemic adenoviral infections in military recruits have a spectrum of clinical manifestation ranging from colds to severe pneumonia. Typically, however, the manifestations are fever, pharyngeal symptoms, cough, chest pain, headache, and malaise.<sup>98</sup>

Overwhelming pneumonitis may be part of disseminated adenoviral infections in newborn infants and patients with immunodeficiencies, including acquired immunodeficiency syndrome (AIDS). However, the frequent concomitance of other respiratory pathogens in AIDS patients and the high prevalence of asymptomatic adenovirus infection shed doubt on the causal role of the adenovirus in these patients.<sup>102</sup> Adenoviruses are also an important cause of epidemic keratoconjunctivitis.<sup>94,98</sup>

While most adenoviral ARIs are self-limited and uncommonly associated with death or permanent sequelae,<sup>94</sup> adenoviruses alone or associated with other pathogens have been recovered from 20% of fatal cases of LRI in Argentina.<sup>103</sup>

## **PATHOGENESIS AND IMMUNITY**

Adenoviral respiratory disease results from necrosis of cells of airway epithelia, and viremia may result in disseminated infection in immunocompromised persons. Bronchiolitis, interstitial pneumonitis, and mononuclear cell infiltrates are part of the inflammatory process in the lungs. It remains unclear why certain strains are more virulent than others. For example, the genomic variant B7h was associated with the majority of fatal lower respiratory disease in South America.<sup>95</sup>

In addition to lytic infection, adenoviruses may become latent in epithelial and lymphoid cells, which is probably important to maintaining the virus in populations.<sup>94</sup> A possible role of latent adenovirus in the pathogenesis of chronic airway inflammation has been suggested.<sup>94,96,104</sup>

Protection from adenovirus infection and disease is mainly due to type-specific neutralizing antibody, but reinfections, mostly asymptomatic, may occur. A long-lived T-cell immune response develops in most infected immunocompetent persons and is not only responsible for recovery but also is involved in tissue pathologic changes.<sup>94</sup>

## **DIAGNOSIS**

Adenoviruses can be detected in respiratory, ocular, or ear secretions, but clinical correlation is required, because asymptomatic virus shedding is common. Isolation of adenoviruses in cell culture with identification by IF constitutes the standard diagnostic method, but direct detection of viral antigens or viral DNA by PCR in clinical samples is an attractive

rapid alternative.<sup>94</sup> Rapid antigen detection by immunochromatography is around 95% sensitive in comparison with cell culture, and easily can be used in point-of-care diagnosis of adenovirus. However, both conventional and real-time PCR are more sensitive than cell culture is.<sup>105</sup> Positive results by PCR should be interpreted with caution, given the propensity of adenoviruses to cause latency.

Adenoviruses cause a characteristic CPE in a variety of cell lines of human origin, and maintenance of cultures for 2 weeks combined with blind passage (i.e., passage of cells even without obvious CPE to see if it develops after passage) may increase adenovirus recovery.<sup>3,94</sup> Inoculation of cells by centrifugation followed by immunostaining may shorten the detection time.<sup>106</sup>

Several serologic tests can detect antibodies to the common hexon antigen.<sup>94</sup> However, their clinical utility is restricted.

## **TREATMENT**

At present, there is no routine effective antiviral treatment for adenovirus infections. Successful therapy of severe adenoviral infections in immunocompromised patients with IV ribavirin has been reported.<sup>107</sup> Cidofovir has shown some efficacy in the rabbit ocular model of adenoviral infection. Iododeoxyuridine and adenine arabinoside were unsuccessful in the treatment of adenoviral keratoconjunctivitis.<sup>94</sup>

## **PREVENTION AND CONTROL**

A live vaccine consisting of wild-type adenovirus packaged in enteric-coated capsules induces immunity by ensuring enteric infection without infection of the respiratory tree. This approach has been used successfully to vaccinate military recruits against adenoviruses types 4 and 7.<sup>98</sup> Proper sterilization, hand washing, and chlorination can prevent adenovirus spread via tonometers, hands, and swimming pools.

## **■ Coronaviruses**

Coronaviruses are enveloped viruses with distinct virion morphology, displaying widely spaced, long petal-shaped spikes at the surface, that confer a crownlike appearance, the origin of the name *corona*. The envelope contains a long helical nucleocapsid with single, positive-stranded RNA, 27 to 32 kb in size, which is the largest known viral RNA genome.<sup>108</sup> Until very recently, only three human coronaviruses (HCoV) were known to exist: HCoV-229E, HCoV-OC43, and the CoV associated with severe acute respiratory syndrome (SARS-CoV). Recently, two groups in The Netherlands almost simultaneously published studies that resulted in the identification of two new strains of HCoV: HCoV-NL63<sup>109</sup> and HCoV-NL.<sup>110</sup> In addition, PCR primers directed to conserved replicase 1a sequences of animal CoVs led to the identification of yet another HCoV detected in 8.8% of children from New Haven, Connecticut with symptoms of ARI. This agent was designated HCoV-NH and is likely to represent the same species of HCoV-NL and -NL63.<sup>111</sup> On the basis of antigenic and genetic studies, the known human coronaviruses are distributed in three of the four coronavirus groups so far identified. HCoV-229E, -NH, -NL, and -NL63 belong to

group I, HCoV-OC43 belongs to group II, and SARS-CoV is the only known constituent of group IV, while group III contains no known human viruses and consists only of the avian infectious bronchitis virus.

Coronavirus RNA synthesis occurs in the cytoplasm via a negative-strand RNA intermediate. The viral RNA possesses a 5' cap followed by a leader sequence and an untranslated region, with another 3' terminal untranslated region followed by a poly(A) tail. The genome is polycistronic and the synthesis of subgenomic negative-sense RNAs is done by discontinuous transcription to originate a nested set of subgenomic mRNAs that share the 5' leader sequence and overlap at the 3' end. The envelope contains the structural proteins S (spike), M (membrane), E (envelope), and only in the case of some group II coronaviruses, HA (hemagglutinin). The S glycoprotein contains neutralizing and T-cell epitopes and functions as the cell receptor ligand, thereby determining tissue tropism. The M protein is embedded in the envelope and interacts with the N (nucleocapsid) protein during maturation. In addition to the nucleocapsid and envelope proteins, a replicase is present in cells infected by all coronaviruses. New virions assemble by budding through intracellular membranes and are released through vesicles of the secretory pathway.<sup>108</sup>

## HUMAN CORONAVIRUSES UNRELATED TO SARS

HCoV-229E and -OC43 are considered to be second only to rhinoviruses as agents of common colds, causing infections with variable frequency, depending mainly on the detection method and season of the study. Up to 35% of mild upper respiratory tract infections in adults have been attributed to HCoV-229E.<sup>112</sup> While HCoV-229E and -OC43 are documented causes of colds in temperate regions, their impact as causes of respiratory infections in tropical regions has not been defined.

## AGENTS

Human coronaviruses were first isolated in England, almost 40 years ago, in human organ cultures of tracheal and nasal tissues. There have been relatively few field studies based on HCoV isolation in cell culture, likely because these viruses are too fastidious to be propagated, but most respiratory isolates obtained so far have been antigenically similar to either HCoV-229E or -OC43.<sup>112</sup> These agents have the same structural features as the other members of the family. The S protein of HCoV-229E binds to the metalloprotease human aminopeptidase N at the cell surface, and entry is independent of enzymatic activity of the receptor. The hemagglutinin of HCoV-OC43 binds to sialic acid present in glycoproteins on the cell surface and this interaction facilitates infection, but to the best of our knowledge, a specific receptor has not been identified for this agent.<sup>108</sup>

## EPIDEMIOLOGY

HCoVs have been found throughout the world and are considered to be the second most frequent cause of common cold, accounting for an average rate of 15% of respiratory illnesses in the general population in the United States. However, the rates may be quite variable from year to year, ranging from 1% to 35% in years of peak activity. HCoV

infections occur mainly in the winter and spring months, but summer activity has also been documented. During the autumn peak of rhinovirus activity, 8% of the adults with a cold negative for rhinovirus were positive for HCoV by RT-PCR in Charlottesville, VA.<sup>80</sup>

HCoV-229E has caused well-documented winter outbreaks at 2- to 4-year intervals in temperate regions.<sup>112,113</sup> Similarly, winter outbreak of HCoV-OC43 has also been detected in Europe.<sup>114</sup> In contrast, little is known about the prevalence of HCoV-229E and -OC43 in tropical countries. In Brazil, the activity of HCoV-229E as cause of respiratory infections in nonhospitalized children was first documented by serology in the early 1970s, with a seropositivity rate of 26% in adults by complement fixation assay.<sup>115</sup>

## CLINICAL FEATURES

The usual manifestations of HCoV infection are typical common colds. The incubation period tends to be 1 day longer than that for rhinovirus colds, with illness duration of 6 to 7 days. Low-grade fever may occur in up to 20% of the patients, and in addition to nasal symptoms, cough and sore throat occur frequently. More serious infections of the lower respiratory tract caused by HCoV have also been documented, either sporadically in infants with pneumonia and immunocompromised patients, or in up to 33% of previously healthy Marine Corps recruits with pneumonia.<sup>112,113</sup> In addition, HCoV-229E and -OC43 have been recognized in association with influenza-like illnesses in frail elderly patients. Eight of 100 (8%) nasopharyngeal swabs from older patients hospitalized for cardiopulmonary illnesses during the influenza seasonal outbreak in Rochester, N.Y., were positive for HCoV (five for HCoV-229E).<sup>116</sup>

Respiratory HCoV infections have been associated with exacerbations of asthma, chronic bronchitis, and recurrent wheezing in children.<sup>112,113</sup> HCoV was detected by RT-PCR in 38 of 292 (13%) episodes of asthma in children 9 to 11 years old in England.<sup>117</sup> In Brazil, HCoV was detected in respiratory samples from 3 (2 OC43 and 1 229E) of 73 (4%) children younger than 2 years of age who came to the ER with wheezing.<sup>60</sup>

Similarly to HRV, HCoV infections have been frequently recognized in association with otitis media and maxillary sinusitis in children and adults. HCoV was detected by RT-PCR in the middle ear effusion or nasopharyngeal aspirate from 16 of 92 (17%) children with acute otitis media in Finland<sup>84</sup> and in nasal swabs from 3 of 20 adults with acute maxillary sinusitis.<sup>83</sup>

## PATHOGENESIS AND IMMUNITY

There is no convenient small animal model to study the pathogenesis of HCoV, and humans naturally or experimentally infected are the only source of information obtained *in vivo*.

HCoVs are transmitted by the respiratory route, and experimentally infected volunteers shed virus for approximately 5 days, beginning 48 hours after infection, which is approximately the time of onset of symptoms.<sup>112,113</sup> The peak of symptoms occurs 2 to 4 days postinoculation.<sup>112</sup> HCoV-229E is known to infect airway epithelial cells from the apical surface, where the receptor is constitutively expressed, and to

exit productively infected cells through the same route.<sup>118</sup> Ultrastructural studies of nasal epithelium of volunteers experimentally infected with HCoV-229E revealed significantly greater epithelial cell damage, ciliary loss, and cytolysis in virus-inoculated subjects than in sham-inoculated ones on day 3 postinfection.<sup>119</sup>

In the United States, seropositivity to HCoV-OC43 and -229E rises during the first 5 years of life, and around 40% of adults are seropositive. Symptomatic reinfections are possible, despite the presence of antibodies, suggesting rapidly waning immune response or circulation of closely related but antigenically different viruses.<sup>113,120</sup> Several studies indicate that respiratory HCoVs are able to reach the central nervous system.<sup>112,113,120</sup> The recently reported temporal association between HCoV-NH infection and Kawasaki disease<sup>121</sup> awaits confirmation.

## DIAGNOSIS

Laboratory diagnosis in clinical samples by isolation is tedious, because the two best characterized strains of HCoV are difficult to grow in routine cell cultures. Since primers can be developed for relatively constant parts of the genome, RT-PCR-based assays for HCoV-229E and -OC43 have recently become the best alternative to other methods of detection.<sup>80</sup> More recently, a quantitative real-time PCR-based assay for HCoVs has been developed, providing a faster means for detection and determination of viral load with potential applications in clinical studies.<sup>122</sup> Serologic diagnosis of HCoV by EIA is sensitive and specific and has been useful in epidemiologic surveys.<sup>113</sup>

## TREATMENT AND PREVENTION

Intranasal interferon protects against experimental infection with HCoV-229E,<sup>123</sup> but no specific antiviral therapy is available, and treatment of HCoV-induced colds remains largely symptomatic. No vaccines are currently available for HCoV.

## SARS-CORONAVIRUS

SARS was first reported to WHO by Carlo Urbani, a physician working in Hanoi, Vietnam, in February 2003. Retrospective analysis revealed that cases compatible with the new disease had occurred in China starting in November 2002. SARS is caused by a newly recognized coronavirus that emerged in China, subsequently spreading to several other countries in Asia, the Americas, and Europe.<sup>124</sup> Isolation and characterization of the agent was accomplished in record time after the 2002–2003 outbreak started, by four research groups in the WHO laboratory network.<sup>124</sup> In February 2003 a single infected person from the province of Guangdong, China, spent 1 day at a hotel in Hong Kong and transmitted the virus to 16 other people, who in turn seeded outbreaks of SARS in other countries in Asia and in Canada. In a matter of weeks, SARS had affected thousands of people in 25 countries in all continents, causing enormous global impact and intense media coverage, fueled by fast spread via international travel by newly infected individuals.<sup>125</sup> At the time of this writing, no current cases of SARS are registered, and there have been 8117 reported cases of SARS, of which 775 were fatal.<sup>126</sup>

## AGENT

The HCoV that fulfills Koch's postulates as the causative agent of SARS<sup>127</sup> shares structural features and genome organization of the family Coronaviridae (Fig. 59-1). The prompt recognition of the peculiar morphology of a coronavirus in the electron microscopic studies of Vero E6 cells inoculated with oropharyngeal material from a patient was the initial finding that resulted in the identification of SARS-CoV.<sup>128</sup> The viral genome is 29,727 nucleotides in length, with more than 11 open reading frames coding for 23 putative proteins, some of which have unknown functions. SARS-CoV is phylogenetically different and equidistant from all previously known coronaviruses, but isolates from different origins are relatively homogeneous genetically. Genome analysis reveals that SARS-CoV is neither a host-range mutant nor a recombinant of

**FIGURE 59-1** Ultrastructural features of SARS-CoV in Vero E6 cells. *A*, Thin-section electron microscopic view of SARS-CoV nucleocapsids aligned along the membrane of the rough endoplasmic reticulum (arrow) during budding of particles into the cisternae and coronavirus surface projections (arrowhead). *B*, Electron microscopic picture of a negatively stained extracellular particle of SARS-CoV, with the typical club-shaped surface projections. Bars represent 100 nm. (From Ksiazek TG, Erdman D, Goldsmith CS, et al: A novel coronavirus associated with severe acute respiratory syndrome. *N Engl J Med* 348:1953–1966, 2003.)

previously known coronaviruses but rather an independently emerged virus. SARS-CoV seems to have evolved from an animal SARS-like virus, acquiring greater fitness in humans during the course of the outbreaks, probably through the appearance of nucleotide deletions in open reading frame 8.<sup>129</sup> It is also noteworthy that genetic signatures present in the genomes allow for differentiation of isolates obtained from different clusters.<sup>129</sup> The replicative cycle of SARS-CoV is thought to follow the same main steps as other coronaviruses.

## EPIDEMIOLOGY

SARS coronavirus (SARS-CoV) probably emerged around November 2002 in the province of Guangdong, China, where there was no serologic evidence of infection caused by this virus in sera of healthy humans sampled prior to that time.<sup>130</sup> At the beginning of the outbreak, many affected individuals in Guangdong were directly or indirectly involved with game trade, and indeed, palm civets and raccoon dogs from wild-game markets in the area were later found to harbor a CoV 99% homologous to SARS-CoV at the nucleotide level. This suggests that animal-to-human interspecies transmission was involved in the outbreak, providing the source of an agent that later adapted to efficient human-to-human transmission.<sup>131,132</sup> Interestingly, shortly after the lifting of a wildlife trade ban that originally had been imposed to control the SARS outbreak, new cases were again detected in Guangdong, all of them caused by viruses newly introduced from animals. Since the ban was reinstalled, there have been no further naturally acquired human cases of SARS in Guangdong.<sup>131</sup>

Remarkably, 1.8% of 938 serum samples from adults recruited in 2001 in Hong Kong tested positive for SARS-CoV antibodies, suggesting that a small proportion of healthy people from Hong Kong, as opposed to Guangdong, China, had been exposed to SARS-related viruses at least 2 years before the outbreak.<sup>133</sup> It is probable that SARS-CoV precursors previously crossed the species barrier and may even have caused subclinical human infection, but perhaps only occasionally this event generated strains adapted to successful human-to-human transmission.<sup>131</sup>

SARS-CoV is mainly transmitted between humans by the deposition of infected droplets or aerosols on the respiratory epithelium. The number of confirmed secondary cases generated by one index case of SARS is relatively low, ranging from 2.2 to 3.7, suggesting relatively inefficient transmission. In addition, transmission is infrequent during the first 5 days of illness, partly because of the low viral load in respiratory secretions during that phase. For reasons not completely understood, some SARS patients, identified as superspreaders, disproportionately contribute to the generation of a high number of secondary cases.<sup>131</sup> Excretion of SARS-CoV in sputa and stools may average 21 and 27 days, respectively, after symptom onset, but an excretion period as prolonged as 126 days has been documented in stools.<sup>134</sup> Such prolonged shedding of virus in feces raises the possibility of oral-fecal transmission and, in fact, one outbreak of SARS was attributed to a faulty sewage system.<sup>131</sup>

Case-fatality rates estimated based on cases admitted to hospital have been around 13% for patients younger than age 60 and 43% for those older than age 60 years. However, it is likely that case-fatality rates based on all infections occurring in the community would be lower.<sup>135</sup>

Transmission of SARS-CoV among health-care workers and between patients in the hospital setting played a pivotal role in outbreak propagation. Analysis of data from initial outbreaks indicates that close contact is the most important factor leading to nosocomial transmission of this agent. Despite the lack of complete studies on the sensitivity of SARS-CoV to different environmental conditions, there have been reports of SARS-CoV persisting for up to 2 days on environmental surfaces and 4 days in diarrheal stools.<sup>136</sup>

## CLINICAL FEATURES

The median incubation period of SARS is 4 to 6 days. Clinical symptoms and signs of SARS appear 2 to 10 days after exposure, and systemic symptoms, such as fever, chills, myalgia, and malaise, usually appear first. Respiratory symptoms appear 2 to 7 days later, represented most frequently by nonproductive cough, dyspnea, chest pain, headache, and sore throat. Diarrhea and vomiting may occur. Chest radiograms frequently reveal infiltrates consistent with viral pneumonia, consisting mostly of consolidations and ground-glass opacifications. Computed tomography (CT) scans in patients with normal or equivocal chest radiograms may show unilobar or multilobar abnormalities. Fever generally subsides in 48 hours, but one or two relapses within 8 to 15 days are frequently observed. Lymphopenia with reduction of both CD4+ and CD8+ cells, slight decrease in platelet counts, prolonged coagulation profile, and elevated serum enzymes (lactic dehydrogenase [LDH], creatinine kinase [CK], and C-reactive protein [CRP]) are often observed. Around one third of patients may have CD4+ lymphocyte counts below 200 cells/mm<sup>3</sup> and higher susceptibility to secondary infections. Watery diarrhea with an average of six evacuations per day is common.<sup>130,131,137</sup>

Radiologic worsening of the pulmonary lesions seen at admission, with or without appearance of new lesions, is a frequent observation, with development of diffuse ground-glass changes frequently heralding the development of acute respiratory distress syndrome (ARDS). Hypoxemia is noted in approximately half of the patients at around 9 days after the onset of symptoms, and a high proportion of those admitted to the intensive care unit (ICU), especially older males, require mechanical ventilation around day 13. Development of spontaneous pneumomediastinum during follow-up is not uncommon, probably as a consequence of ruptured peripheral lung lesions into the pleural space.<sup>130</sup>

Prognosis is related to the level of viral replication in tissues, and patients with high viral loads in serum, nasopharyngeal aspirates, or feces, as well as those in whom virus can be detected from multiple sites, tend to have poor clinical outcome.<sup>131</sup> In addition to old age and severe underlying diseases, CK and CRP levels have been identified as predictors of poor outcome.<sup>138</sup>

## PATHOGENESIS AND IMMUNITY

The N-terminal portion of the spike glycoprotein is needed for virus attachment to the virus receptor, identified as the metalloproteinase angiotensin-converting enzyme homolog (ACE-2),<sup>139</sup> but it is unclear whether the mechanism of entry is contingent on pH-dependent endocytosis.<sup>131</sup> Some inconsistencies between ACE-2 and SARS-CoV tissue distribution suggest that ACE-2 may not be the only receptor, or that a coreceptor molecule may be needed for cell infection.

SARS-CoV spike protein can also bind the dendritic cell-specific C-type lectin intercellular adhesion molecule 3—grabbing nonintegrin (DC-SIGN), which does not result in dendritic cell infection by the agent but allows for SARS-CoV to be transported to susceptible target cells elsewhere.<sup>140</sup>

SARS-CoV has been detected in studies using different combinations of immunohistochemistry, in situ hybridization, and electron microscopy in pneumocytes and on the apical surface of enterocytes. Marked inflammatory infiltrates and mucosal atrophy have not been observed in the intestine, and the pathogenesis of the SARS-CoV-related diarrhea remains largely unknown.<sup>131</sup>

SARS-CoV viral load in the upper airways is low in the 4 initial days, with the peak at day 10 of illness. Quantitative RT-PCR for SARS-CoV in nasopharyngeal aspirates from patients who tested positive at admission revealed viral loads around  $10^5$  copies/mL on days 5 and 15 after clinical onset, and peak  $10^7$  copies/mL on day 10.<sup>130</sup> Higher viral loads can be detected in the lower respiratory tract than in the upper airways. Pulmonary tissue shows diffuse alveolar damage, mixed infiltrate, lung edema, hyaline membrane, abundant macrophages in alveoli and interstitium, and syncytia formation.

Besides respiratory secretions and stools, SARS-CoV can be detected in urine in up to 30% of patients, with titers averaging  $10^{4.4}$  copies/mL, in association with abnormal urinalysis results.<sup>141</sup>

The effect of SARS-CoV infection on the immune system is highlighted by pronounced T-cell lymphopenia and elevation of several inflammatory cytokines (IL-1 $\beta$ , IL-6, and IL-12) and chemokines (MCP-1 and IP-10) observed in SARS patients. While MCP-1 is likely to be involved in the lung monocytic/macrophagic infiltrate, its role is not firmly established, since other viral diseases that are associated with elevated MCP-1, such as influenza, do not include such prominent histologic features. In addition, since immunologic markers in the peripheral blood may not reflect what happens in the microenvironment of the lung, the pathogenic importance of these findings is not clear. Co-inheritance of HLA-B\*0703 and -B60 is higher among SARS patients than in the general population, favoring a role for the genetic background in susceptibility to SARS-CoV.<sup>131</sup> The pathogenesis of the T-cell lymphopenia remains unknown.

Seroconversion has been documented in 93% of the patients at around 20 days and the rise in IgG titers correlates with decrease in viral load.<sup>130</sup> Paradoxically, clinical worsening also occurs during this phase, suggesting that, rather than unchecked viral replication, immunopathologic factors may be responsible for the lung lesions.<sup>130</sup>

While infection in experimental animals, such as cynomolgus macaques, ferrets, cats, golden Syrian hamsters, mice, and African green monkeys, does not induce disease that mimics that in humans, these models are important for studies of pathogenesis and development of vaccines and therapy.<sup>129</sup> In addition, the development of an infectious cDNA clone of SARS-CoV should permit reverse genetics experiments and may help elucidate determinants of viral pathogenesis.<sup>142</sup>

## DIAGNOSIS

Low viral loads in the upper respiratory tract in the first few days of illness account for the relatively poor sensitivity

(35% to 65%) of first-generation RT-PCR for diagnosis in that period. SARS-CoV is detectable by RT-PCR in nasopharyngeal aspirates in only one third of patients at presentation and in two thirds at day 14. RT-PCR may be positive for SARS-CoV in stools from as much as 97% of patients at day 14, and in urine in 42% of samples at day 15.<sup>130</sup> Testing multiple nasopharyngeal, serum, and fecal samples increases the sensitivity of the diagnosis by RT-PCR.<sup>143,144</sup>

To overcome the low sensitivity of conventional RT-PCR, quantitative real-time PCR-based assays for SARS-CoV have been developed that improve sensitivity and turnaround time, allow for amplification and analysis to be done in a closed system, and thus reduce cross-contamination. In addition, the capability of the assay to quantitate viral load has contributed not only to understanding viral pathogenesis but also to predicting outcome, since high viral loads are associated with poor prognosis.<sup>143</sup>

The ability to grow SARS-CoV in Vero E6 cell cultures was critical to identifying the agent. SARS-CoV can be recovered by isolation from respiratory secretions, feces, and urine in the first 3 weeks of illness, but the overall sensitivity is relatively low and recovery is more likely to be successful from respiratory secretions than from stools and urine.<sup>143</sup> Recent small outbreaks of SARS-CoV originating in laboratories<sup>143</sup> have heightened concern about laboratory safety issues regarding SARS specimens. The WHO guidelines for biosafety in the diagnosis of SARS (updates available at the WHO web site) recommend that propagation of SARS-CoV in cell culture for isolation or for preparation of viral stocks and cell slides be performed in biosafety level 3 (BSL3) laboratories, whereas handling serum and blood specimens for routine tests and serology can be performed in BSL2 laboratories. Nucleic acid extraction procedures, inoculation of bacterial or mycologic cultures, and preparation of sample smears can be done in BSL2 laboratories, observing BSL3 work practices (use of safety cabinets, sealed centrifuges, protective equipment, 5% bleach spillage decontamination, and proper waste disposal).

Although not useful for early diagnosis, seroconversion determined by IFA or EIA remains the gold standard for confirming SARS diagnosis. IgG seroconversion is detectable in over 90% of patients at around day 28.<sup>130</sup> Antibody cross-reaction with other human coronaviruses, however rare, remains a possibility; therefore, confirmation of positive serology by an independent neutralization assay should be performed if available.<sup>143</sup>

## TREATMENT

The main component of treatment of SARS patients is supportive therapy, chiefly the management of hypoxemia and ARDS. During the 2003 outbreak, treatment included a broad-spectrum antiviral agent (ribavirin) and immunosuppressive doses of corticosteroids, aimed at reducing the immunopathologic damage to the lungs. The use of high-dose steroid therapy is controversial and for the most part supported by anecdotal evidence, whereas the use of ribavirin is based on the broad antiviral spectrum of the drug. However, SARS-CoV is only modestly susceptible to ribavirin *in vitro*, and therapeutic doses are difficult to achieve clinically. Since it became possible to grow SARS-CoV in culture, many potential antiviral compounds have been evaluated *in vitro*, but just a few have been tested in animal models and even fewer are in clinical testing.<sup>131</sup>

Interferons (IFN- $\alpha$ 1/n3, leukocytic IFN- $\alpha$ , IFN- $\beta$ ) and HIV protease inhibitors were consistently active in vitro and may be considered for animal testing and clinical trials.<sup>131</sup>

The resolution of the structure of SARS-CoV principal protease has prompted studies of the inhibitory capacity of known anti-HIV protease inhibitors for treatment of SARS. In one open-label study, a combination of HIV protease inhibitor (lopinavir plus pharmacokinetic booster ritonavir) and ribavirin was used to treat SARS patients and the outcomes were compared with historical controls treated with ribavirin alone. At day 21 after onset of symptoms, development of ARDS or death was significantly less frequent in the group treated with the combination (2.3%) than in historical controls (28.8%). In addition, peak viral loads in respiratory samples and stools were reduced in the group treated with the combination as compared with controls.<sup>145</sup> However, since there were differences in outcome predictors, such as sex, platelet counts, and LDH levels, between the two groups, these results should be interpreted with caution.

A preliminary open-label study found that a restricted number of patients treated with subcutaneous interferon alfacon-1 in association with corticosteroids showed reduced oxygen-saturation impairment and faster resolution of radiographic chest findings than those treated with corticosteroids alone.<sup>146</sup>

Convalescent plasma has also been tested in the treatment of SARS patients. In one preliminary uncontrolled study, convalescent plasma may have reduced the frequency of poor outcome when given before 14 days of illness.<sup>147</sup>

## PREVENTION

It is impossible to predict whether naturally reemerging SARS-CoV would be likely to cause a global outbreak. Nevertheless, a vaccine for this agent would be relevant for high-risk individuals, such as workers in laboratories, hospitals, and game-animal farming. Therefore, considerable effort has been directed at developing such a vaccine. It has been shown that SARS-CoV spike protein produced in bacteria and expressed on chimeric parainfluenza virus, as well as spike protein-encoding DNA, induced neutralizing antibodies and protected experimental animals from challenge with live virus. At present, no SARS-CoV vaccine is available for human use. Therefore, in the absence of person-to-person transmission of SARS-CoV worldwide, prevention of future outbreaks of SARS requires careful surveillance. The goal is to maximize early detection of new cases of SARS to implement control measures, thereby minimizing social disruption.<sup>131</sup>

To reach this goal, the CDC recommends testing for SARS-CoV in patients who require hospitalization for radiographically confirmed pneumonia or ARDS without identifiable etiology and who have one of the following risk factors in the 10 days before the onset of illness: (1) travel to mainland China, Hong Kong, or Taiwan, or close contact with an ill person with a history of recent travel to one of these areas, or (2) employment in an occupation associated with a risk for SARS-CoV exposure (e.g., health-care worker with direct patient contact; worker in a laboratory that contains live SARS-CoV), or (3) belonging to a cluster of cases of atypical pneumonia without an alternative diagnosis (updates on these recommendations are made available at the CDC web site <http://www.cdc.gov/ncidod/sars>).

During times of overt SARS activity, prevention of human-to-human transmission is pivotal to curtailing outbreaks. Although SARS infectiousness relative to the onset and termination of clinical symptoms has not been accurately determined, it is clear that shortening the time from onset to hospital admission and isolation reduces the risk of transmission, thus contributing substantially to curtailing of outbreaks. Identification of new cases through contact tracing played an important role in the control of the outbreaks registered so far. Stringent isolation procedures must be adopted for confirmed and suspected cases, which require a high level of alertness among health-care workers for early identification of SARS cases. The scenario may be further complicated in situations in which other diseases such as influenza and Hantavirus pulmonary infections may occur simultaneously.<sup>135</sup>

Rates of transmission of SARS-CoV among health-care workers vary, depending on stringency of control measures adopted, presence of so-called superspreaders in the hospital, and kind of activities carried out by personnel, especially as related to proximity to the index case. Assisting during intubation, suctioning, and manipulating ventilatory apparatuses seem to be high-risk activities. While studies conducted in different settings have produced conflicting results, one study in Toronto found that up to 25% of the nurses who cared for SARS patients in critical care units became infected.<sup>148</sup> The presence of severe watery diarrhea may add to the challenge for the infection control team.<sup>130</sup> An updated set of recommendations for health-care and laboratory personnel is available at the CDC web site (<http://www.cdc.gov/ncidod/sars>).

## METAPNEUMOVIRUSES

A new paramyxovirus was described in The Netherlands in 2001, in association with respiratory illness in children. The agent was first detected by analysis of previously unidentifiable viral isolates that induced cytopathic effect in LLC-MK2 cell cultures. The isolates were recovered over a 10-year period in respiratory secretions from 28 children with ARI occurring in the winter time. Electron microscopy of cell culture isolates revealed paramyxovirus-like particles, and RNA sequencing revealed genome sequences and organization consistent with a paramyxovirus of the subfamily *Pneumovirinae*, most closely related to avian pneumovirus of the genus *Metapneumovirus*. Rather than an avian virus that can also infect humans, this agent is now recognized as a primarily human pathogen, and thus has been named human metapneumovirus (HMPV).<sup>156,157</sup> HMPV antibodies detected in sera collected in 1958 in The Netherlands indicate that this agent has been in circulation for at least 4 to 5 decades.<sup>156</sup>

## AGENT

HMPV particles are enveloped, pleomorphic, spherical, and filamentous particles, with a mean diameter of about 209 nm.<sup>156,157</sup> Complete genome sequences of HMPV are available and, in contrast to the genomic organization of pneumoviruses, metapneumoviruses have different positioning of the genes between M and L and lack NS1 and NS2 genes.<sup>156,158</sup> Similar to HRSV, genetic and antigenic studies indicate that HMPV isolates cluster into two main serotype

named A and B, with N gene sequences 83% to 85% similar at the nucleotide level, each subgroup including two genetic lineages (A1, A2, B1, and B2).<sup>156,159,160</sup> Both are globally distributed. There have been no detailed studies of the HMPV replication cycle, but it is likely to be similar to that of other human paramyxoviruses.

## EPIDEMIOLOGY

HMPV is a frequent cause of community-acquired ARI in children and adults in all continents, although with variable incidence in different settings.<sup>157,159,161–169</sup> In the United States, HMPV has been reported in up to 20% of lower respiratory tract illnesses whose etiology would have been unidentifiable prior to the development of assays for the detection of HMPV.<sup>170</sup> In Canada, during the 2001–2002 winter season, HMPV was detected in 15% of patients of all age groups from four different provinces.<sup>167</sup>

Similar to HRSV, HMPV infections are more frequent in the colder months in temperate regions, and different strains of both subgroups A and B cocirculate during the same year.<sup>157,162</sup> However, only limited knowledge is available about HMPV seasonality in more tropical climates. Peaks of HMPV activity have been documented in the spring/summer in Hong Kong,<sup>171</sup> while in South Africa HMPV has been detected in 6% to 9% of children with ARI admitted to hospitals in the winter season.<sup>161,165</sup> HMPV was detected alone or simultaneously with RSV in 24% of children younger than 3 years of age admitted to health-care facilities in Aracaju, northeast Brazil, in the months of April and May, 2002.<sup>164</sup> Interestingly, HMPV was not detected by the same methods in that same city, in the following year.<sup>166</sup> This apparent variability in HMPV incidence from year to year has also been observed in studies conducted in Argentina<sup>168</sup> and Italy, where HMPV frequencies varied from 7% to 43% in three consecutive annual respiratory virus seasons.<sup>172</sup> Long-term prospective studies will be needed to establish whether there is a seasonal pattern in HMPV circulation in tropical regions of the world.

## CLINICAL FEATURES

Clinically, HMPV infections resemble closely those caused by HRSV, ranging from mild upper ARI to severe bronchiolitis and pneumonia. The median age of children hospitalized with HMPV infection is older than those with HRSV. HRSV in hospitalized infants and young children may require intensive care and mechanical ventilation,<sup>156,173,174</sup> and dual infection with HMPV and HRSV appears to increase the likelihood of severe illness.<sup>175,176</sup> The most frequent symptoms in all age groups are fever, dyspnea, cough, wheezing/stridor, rhinitis, and sore throat.<sup>162,173</sup> All infected children in one study had either pneumonia or bronchiolitis, frequently accompanied by otitis media.<sup>162</sup> HMPV may cause more serious infections in patients with comorbid or immunosuppressive conditions, as well as in the very young and the elderly.<sup>162,167</sup> In one study, all individuals older than 65 with lower respiratory infection caused by HMPV had at least one underlying chronic or debilitating condition, including lymphoma, leukemia, or neurologic or cardiovascular diseases.<sup>162</sup>

HMPV infection in adults may present as influenza-like illness, acute bronchitis, or common cold.<sup>162</sup> In England, in

the winter of 2000–2001, HMPV was detected by RT-PCR in association with 2.2% of samples taken from patients in all age groups with influenza-like illnesses negative for HRSV and influenza viruses.<sup>159</sup>

HMPV has been increasingly recognized as cause of acute wheezing in children. One study conducted in Finland found HMPV in 8% of wheezing children, who presented significantly higher levels of IL-8 in nasal secretions as compared to children with HRSV-associated wheezing.<sup>174</sup> A study conducted in Brazil found that 47% of the children with HMPV had wheezing and 31% had chest indrawing.<sup>164</sup> Previous history of asthma has been more frequently associated with HMPV than with HRSV infection and HMPV-infected patients are more often treated with bronchodilators and corticosteroids than HRSV-infected patients.<sup>173</sup>

## PATHOGENESIS AND IMMUNOLOGY

Little is known about specific mechanisms of pathogenesis and host immune response in HMPV infections. HMPV is a pathogen of both the upper and lower respiratory tracts.<sup>162</sup> HMPV replicates efficiently in the respiratory tract of monkeys, with virus shedding peaking between days 2 and 8 following infection.<sup>156</sup> Serologic data indicates that HMPV infects young individuals, and by the age of 5 virtually all children have become seropositive for the agent; reinfections at later ages are common.<sup>156,157,159</sup>

Interestingly, coinfection with HMPV has been reported to correlate with increased severity of HRSV infections. A study conducted in the United Kingdom found that this coinfection caused a tenfold increase in the relative risk of admission to the ICU for mechanical ventilation in children under 2 with HRSV bronchiolitis.<sup>173</sup> A similar finding was also reported in Germany.<sup>176</sup>

## DIAGNOSIS

HMPV can be isolated in LLC-MK2 cells from nasal aspirates or nasopharyngeal swabs. The cytopathic effect, characteristically negative on hemadsorption testing, develops usually late after inoculation (up to 23 days).<sup>160</sup> Sensitive RT-PCR assays for this agent have been developed in many different laboratories and have rapidly become standard for HMPV diagnosis.<sup>159,169</sup> A real-time PCR assay for HMPV showed to be more sensitive than conventional RT-PCR, even when hybridization was used to increase sensitivity of the detection of amplicons generated by the conventional method.<sup>169</sup> Using real-time PCR, HMPV was detected in 10% of 329 samples collected from patients with ARI in Australia from March to October 2001 that were negative for other pathogens.<sup>169</sup>

## TREATMENT, PREVENTION, AND CONTROL

Other than supportive measures, oxygen therapy, bronchodilators, corticosteroids and mechanical ventilation, there is no specific antiviral treatment for this agent.<sup>173</sup> Ribavirin is inhibitory for HMPV *in vitro*.<sup>176</sup> Although a HMPV vaccine is not available at this time, the demonstration that hamsters, ferrets, and African green monkeys are susceptible to infection by HMPV, and that hamsters vaccinated with serotype A

were protected from challenge with either A or B HMPV serotypes opens possibilities for HMPV vaccine design.<sup>176</sup> Humanized neutralizing monoclonal antibody to F protein is active in experimentally infected animals.<sup>177</sup>

# Enterovirus Infections, Including Poliomyelitis

MARK A. PALLANSCH  
HAMID JAFARI

## INTRODUCTION

Enteroviruses are among the most common of human viruses, possibly infecting a billion or more persons annually worldwide. Most infections are largely inapparent, but enteroviruses may cause a wide spectrum of acute disease, including mild upper respiratory illness (common cold), febrile rash (hand-foot-and-mouth disease and herpangina), conjunctivitis, aseptic meningitis, pleurodynia, myocarditis, encephalitis, acute flaccid paralysis (paralytic poliomyelitis), and neonatal sepsis-like disease.<sup>1,2</sup> Enterovirus infections result in hundreds of thousands of hospitalizations per year in the developed world, with aseptic meningitis accounting for the vast majority of these cases. The disease burden in the developing world of the tropics is poorly estimated, with the exception of poliomyelitis. Enterovirus infections are more common in most developing countries, so it is reasonable to assume that significant morbidity can be attributed to these viruses globally.

Poliomyelitis is the best described enterovirus disease found in the tropics and is probably a disease of antiquity. It was only by the mid-19th century, however, when the Industrial Revolution brought increased urbanization to Europe and North America that larger and more frequent outbreaks of poliomyelitis began in these regions. From the late 1800s, outbreaks were occurring in several European countries and in the United States, and they remained a dominant public health problem in the developed world for the first half of the 20th century. It was only much later that the disease burden due to polio in the developing world, particularly the tropics, was fully appreciated. At the time that the polio vaccines first became available in the 1960s, it is possible that more than 500,000 children a year were paralyzed by poliovirus infection every year, mostly in the developing countries of the tropics.

The knowledge gained about the nature of enteroviruses and the spectrum of clinical disease largely has followed the progress made with studies of polioviruses. Despite this progress, much remains to be learned about the differences found in the tropics that affect the epidemiology and disease burden in these areas.

## AGENTS

Enteroviruses are members of the genus *Enterovirus* in the family Picornaviridae and are among the simplest viruses in terms of genetic complexity and size.<sup>3</sup> All are small, round, 30-nm particles with icosahedral symmetry and no lipid envelope. The infectious particles are relatively heat-resistant, resistant to acid pH (which distinguishes them from rhinoviruses), and also resistant to many common detergents and disinfectants, including most soaps, nonionic detergents, ethanol, ether, chloroform, and other lipid solvents. The virus is stable for weeks or more at 4°C and for days at room temperature; however, the virus is readily inactivated by desiccation, ultraviolet light, heat, formaldehyde, and free chlorine.<sup>4,5</sup> The genomic RNA is infectious and serves as messenger RNA for viral protein synthesis. The RNA is translated in a single open reading frame into one large polypeptide, which is then processed through proteolytic cleavage by two distinct virus-encoded proteases into the functional viral proteins.<sup>6</sup>

Historically, the classification of enteroviruses into the subgroups of polioviruses, coxsackieviruses A and B, and echoviruses was based on the empirical observations of their association with some clinical syndromes, susceptibility to infection or disease, tissue tropism, nature of disease in suckling mice, growth in certain specific cell cultures, and in some cases antigenic similarities.<sup>7</sup> Using these criteria, 64 different serotypes were recognized and classified, despite the fact that several antigenically related viruses had different pathogenic properties in mice. This last discrepancy eventually led to the last four viruses being designated only as enterovirus 68–71.<sup>8</sup> A more satisfactory resolution and a completely new classification followed from the advent of comprehensive genetic studies. The complete RNA genetic sequences for all the recognized enteroviruses have been determined,<sup>9</sup> which has allowed a more detailed description and comparison among these viruses.<sup>10</sup> From these new data and to avoid the inconsistencies of the previous classification scheme, the human enteroviruses have been reclassified into five species: A–D and poliovirus.<sup>11</sup> More recent characterization of previously unidentified enteroviruses and increased emphasis on genetic relationships rather than clinical disease has resulted in the proposal that the three polioviruses be reclassified as members of human enterovirus species C.<sup>12</sup> The new classification is given in Table 60-1.

Continued characterization of enterovirus clinical isolates has also identified many new members of the genus, with the naming continuing from enterovirus 73 sequentially.<sup>13–16</sup> These have been assigned to one of the four species and are included in Table 60-1 for reference. At this time, very little is known about any distinctive clinical or epidemiologic features of these new viruses, but it is clear that there are likely to be many more of these described with the wider application of sequencing studies to viruses from the developing world. Also as a part of these studies, it was demonstrated that echoviruses 22 and 23 are genetically distinct from the enteroviruses,<sup>17</sup> and they have been reclassified as members of the new picornavirus genus, *Parechovirus*, and renamed human parechoviruses 1 and 2, respectively. In addition to the members of the genera *Enterovirus* and *Parechovirus*, at least three more genera in this virus family have members that infect humans: *Rhinovirus*, *Kobuvirus*, and *Hepatovirus* (hepatitis A virus).

**Table 60-1 Proposed Species Taxonomy for Genus Enterovirus**

Species	Serotypes
Enterovirus A (EV-A)	CAV2–8, 10, 12, 14, 16 EV71, 76, 89–92
Enterovirus B (EV-B)	CAV9, CBV1–6 E1–7, 9, 11–21, 24–27, 29–33 EV69, 73–75, 77–88, 93–95
Enterovirus C (EV-C)	CAV1, 11, 13, 17, 19–22, 24 EV96 PV1–3*
Enterovirus D (EV-D)	EV68, 70

CAV, coxsackievirus A; CBV, coxsackievirus B; E, echovirus; EV, enterovirus; PV, poliovirus.

\*Proposed.

The genetic diversity and groupings evident from genomic sequence analysis are also correlated with the antigenic properties of the viruses. These antigenic groupings, which form the basis of the serotype definition for these viruses, are the primary means of distinguishing different enterovirus isolates and are also important for issues of immunity and disease protection. Antisera to each of the viruses raised in animals are usually type specific and provide reference reagents for the serotype determination of the enterovirus isolates.<sup>18</sup> Antigenic differences among isolates in the same serotype can be very complex, but variation at one or several epitopes does not change the serotype as determined by polyclonal antibodies or host response. It should be emphasized that the great diversity of serotypes of enteroviruses presents considerable problems for laboratory diagnosis and epidemiologic investigations, but the serotype usually has minimal importance to the diagnosis and clinical management of an individual patient.

## EPIDEMIOLOGY

The patterns of virus shedding and routes of transmission for enteroviruses are consistent with only a few exceptions.<sup>19</sup> The virus is isolated in the highest titer and for the longest time, often several weeks, in stool specimens but can also be isolated from respiratory secretions. Therefore, both fecal-oral transmission and spread by contact with respiratory secretions (person-to-person, fomites, and large-particle aerosol) are considered the most important modes of transmission for these viruses. The relative importance of the different modes probably varies with the virus and the environmental setting. In addition, enteroviruses that cause a vesicular exanthem can, presumably, be spread by direct or indirect contact with vesicular fluid that contains infectious virus. Another exception to the usual modes of enterovirus transmission are the agents of acute hemorrhagic conjunctivitis: enterovirus 70 (EV70) and coxsackievirus A24 variant (CAV24). These two viruses are seldom isolated from respiratory tract or stool specimens and are probably spread primarily by direct or indirect contact with eye secretions, including fomites.<sup>20</sup> Enteroviruses are efficiently amplified and transmitted among humans without intermediaries such as arthropods or other animals. Although several species of nonhuman primates may

become experimentally or even naturally infected with some human enteroviruses,<sup>21</sup> including poliovirus, there is no evidence that they play any significant role in virus circulation or constitute an effective animal reservoir.

In tropical regions, especially where sanitation is poor, the efficiency of transmission is high. Consequently, not only is the overall prevalence of enterovirus infections higher, but also the average age of infection is younger. During infancy and preschool age, children get frequent infections with many enteroviruses.<sup>22–24</sup> It is not uncommon in these areas to detect two or three simultaneous infections of different enterovirus serotypes, often causing no disease. Since children likely become infected with nearly all enteroviruses in the tropics, most adults are immune and nearly all babies are born with maternal antibodies to most enteroviruses.<sup>25,26</sup> Normally, neonates not protected by maternal antibodies are at risk for serious illness when infected by enteroviruses. Because of the protective maternal antibodies, neonatal enterovirus disease is extremely rare in the tropics, despite the high prevalence of enterovirus infections in older children. In contrast, in temperate regions where the overall prevalence of enterovirus infections and maternal antibodies are much lower, neonatal enterovirus diseases are relatively more common.<sup>27</sup>

It is important to note that shedding may be intermittent and is affected by the immune status of the individual. Past natural infection with the same enterovirus serotype, and immunization in the case of poliovirus, serves to significantly reduce the extent and duration of virus shedding.<sup>28,29</sup> Immunity will protect against disease but does not form an absolute block that will prevent future infection. Therefore, immune individuals can also contribute to virus transmission, while not being at risk for significant disease. This makes it difficult to track the extent of virus transmission by only observing disease incidence.

Enteroviruses are prevalent worldwide, but in communities with clean food and water, good hygiene, and safe disposal of excreta, the transmission is much less intense; therefore, the incidence is lower, and infections occur over a broader age range, including adults.<sup>2</sup> In temperate regions a seasonal pattern is prominent, with increased prevalence in summer and autumn and low prevalence in winter and spring. In the tropics the prevalence is also much higher during the warm and wet seasons than in the cooler months; however, seasonal differences are less prominent and infections are prevalent throughout the year.<sup>22,23,30,31</sup>

An important concept in understanding the epidemiology of the enteroviruses is variation: by serotype, by time, by geographic location, and by disease. This concept is illustrated in surveillance studies of nonpolio enterovirus infections.<sup>19</sup> There are two primary patterns of enterovirus prevalence: endemic and epidemic. The epidemic pattern is characterized by sharp peaks in numbers of isolations followed by periods with few isolations. Individual peaks of activity may be a single year or a few years. By contrast, viruses that show an endemic pattern are isolated in about the same numbers every year, with only rare peaks observed. Where surveillance data exist, similar endemic and epidemic patterns are seen for most enteroviruses, but are often not reflected in changes of disease incidence.

Many studies have examined the prevalence of antibodies to the enteroviruses in specific populations.<sup>32,33</sup> Several important

conclusions can be drawn from these serosurveys. First, the number of persons who have neutralizing antibody to any given enterovirus is large, indicating a high incidence of past infection. Second, infections with one serotype of enterovirus can boost the antibody titers to other enterovirus serotypes as measured by either immunoglobulin M (IgM) or neutralization. The pattern of the heterotypic response varies by serotype and among individuals. Third, the pattern of antibody prevalence by serotype varies by geographic location, by time, and by age. Thus, prevalence data from different years and locations are not directly comparable.

The epidemiology of poliovirus infection has been radically altered by the widespread use of both inactivated polio vaccine (IPV) and oral polio vaccine (OPV). The recent activities of the Polio Eradication Initiative have eliminated endemic poliovirus from most of the world.<sup>34</sup> Since 1988, poliomyelitis from wild poliovirus has declined dramatically and in the year 2004 remains endemic in only six countries in Africa, the Middle East, and Southern Asia (Fig. 60-1). Three regions of the world—the Americas, the Western Pacific, and Europe—have been certified to be free of endemic poliovirus transmission.<sup>35</sup> It is also highly likely that one of the three serotypes of wild poliovirus (type 2) has already been eliminated from the entire world.<sup>36</sup> The only remaining wild type 2 viruses are now found in laboratories and vaccine manufacturing facilities.

Even in areas that are no longer endemic, poliomyelitis can still be observed associated with exposure to OPV, either among vaccine recipients (usually with the first dose) or their contacts.<sup>37–39</sup> The incidence of disease associated with use of OPV is estimated to be 1 case for every 750,000 doses among first-dose recipients and 1 case for every 6.4 million doses (all doses) among contacts.<sup>40</sup> Many developed countries have switched to IPV to eliminate these few remaining cases of vaccine-associated paralytic poliomyelitis.

Recently, five outbreaks of poliomyelitis have been documented that were caused by Sabin OPV strains that had acquired the capacity to cause paralysis and be transmitted among human populations (see later discussion under Polio Eradication). These events are extremely rare and occur only in populations with low immunization coverage. Polio-free countries that have populations with low OPV immunization rates are at risk of importation and spread of wild poliovirus strains as well as emergence of circulating vaccine-derived polioviruses.

Any area with endemic wild polioviruses can serve as a reservoir for reintroduction of poliovirus to areas that have no endemic poliovirus circulation.<sup>41</sup> In addition to several documented long-range importations over the past 25 years, wild poliovirus recently spread from an endemic reservoir in Nigeria to cause cases in 12 additional countries during 2004 and re-establish virus circulation in six of these.<sup>42</sup> The frequency and ease of international travel probably results in frequent introduction of wild poliovirus into all regions of the world. High rates of polio vaccine coverage are necessary to prevent poliomyelitis epidemics.

A powerful tool for tracking the circulation of wild poliovirus strains is the genomic sequence characterization of poliovirus isolates. By comparing the genetic changes among poliovirus isolates, their geographic and temporal origins can be determined. For example, sequence analysis has traced the circulation of a particular poliovirus strain throughout endemic

countries, elucidated pathways of transmission during outbreaks, and documented importations from endemic regions into polio-free countries.<sup>43–46</sup> The WHO Poliovirus Laboratory Network of 145 formally accredited poliovirus laboratories provides critical information about wild poliovirus circulation, allowing immunization efforts to be targeted to the virus reservoir areas.<sup>47</sup> In addition, improved sequencing technology has facilitated the analysis of complete genomes of circulating polioviruses. This approach has expanded the understanding of the types of mutations that occur in human populations, including the frequent exchange of genetic material between poliovirus and other enteroviruses.<sup>44,48,49</sup> Similar studies, although with less comprehensive surveillance activities, are now also being applied to nonpolio enterovirus outbreaks as well.<sup>50,51</sup> The result of this molecular epidemiology is a more refined understanding of the complexities of enterovirus transmission and epidemiology.

## CLINICAL SYNDROMES CAUSED BY ENTEROVIRUSES

Enterovirus infections can result in a wide variety of disease syndromes. The most common result of enterovirus infection is either no symptoms or mild upper respiratory tract symptoms.<sup>2,19</sup> Other mild enteroviral illness, consisting of fever, headache, malaise, and occasionally mild gastrointestinal symptoms, may also occur. The gastrointestinal symptoms may be the effect of local infection without viremia. Much less frequently, serious illness brings the patient to the attention of a physician.

It is important to remember that the link between an enterovirus infection and a disease syndrome should be made with caution. Inapparent infections and prolonged excretion of virus, especially in stools, are common. A definitive link cannot be made between infection and disease based solely on isolating virus from the stool of an individual patient. A link can be inferred if the virus is isolated from a site that corresponds to the clinical symptoms and if that site is normally sterile. Most associations between enterovirus infection and disease have been made from studies of outbreaks in which a large number of persons with the same clinical signs and symptoms have evidence of infection with the same serotype. Such studies have clearly demonstrated that enterovirus infection can cause aseptic meningitis, pericarditis, pleurodynia, myocarditis, acute hemorrhagic conjunctivitis (AHC), and encephalitis. When an individual patient has a disease syndrome shown clearly to be associated with enterovirus infection and there is no evidence of involvement by another agent, infection implies probable causation.

The most commonly recognized serious manifestation of enterovirus infection is central nervous system (CNS) disease, usually aseptic meningitis, but sometimes encephalitis or paralysis.<sup>2,19</sup> Although the association between myocarditis and pericarditis and enterovirus infection is clearly established, it is not yet clear how often enterovirus infections are responsible for the disease syndromes. Several studies suggest, but do not clearly show, that enterovirus infection may be associated with a large fraction of cases of acute myocarditis.<sup>52,53</sup> By contrast, different studies have failed to show conclusive evidence for significant involvement of enterovirus infection in idiopathic dilated cardiomyopathies.<sup>54</sup>

1988

2004

**FIGURE 60-1** Global distribution of wild polioviruses and progress in eradication. The maps indicate (*shading*) which countries were endemic for wild poliovirus circulation in the year indicated. In 2004, several countries (*light shading*) that were polio-free for at least 3 years suffered importations of wild poliovirus and circulation was reestablished for a period of at least 6 months.

It is neither necessary nor practical to enumerate all diseases caused by each of the enterovirus serotypes. A limited number of viruses cause a few clinically distinct diseases (e.g., poliomyelitis, AHC, and herpangina). They are relatively easily recognized, and etiologic confirmation by laboratory tests,

if required, can be directed at a few specific enteroviruses. Certain syndromes have varied causes, including some enteroviruses. In such cases etiologic diagnosis is important for giving appropriate treatment or avoiding inappropriate treatment (e.g., meningitis, encephalitis, and myocarditis).

In general, with some notable exceptions, most enteroviruses are capable of causing a variety of clinical disease, and for any specific disease it is difficult to predict the serotype from signs and symptoms alone.

## Poliomyelitis

The term *poliomyelitis* refers to the inflammatory damage (due to infection) of the anterior horn cells of the spinal cord, recognized clinically as acute-onset lower motor neuron paralysis (or paresis) of one or more muscles. When its viral cause was recognized, the agent was called poliovirus, thereby redefining poliomyelitis as spinal cord disease caused specifically by one or another poliovirus serotype. Polioviruses may cause other diseases, but muscle paralysis due to myelitis is the commonest. Until poliovirus infections were controlled by immunization, they were the most common cause of acute flaccid paralysis (AFP). This is no longer the case in most countries.

Poliomyelitis may vary widely in severity, from paresis of one or a few muscles, or paralysis of one or more limbs, to quadriplegia and paralysis of the muscles of respiration (diaphragm, intercostal muscles). In infants and young children, severe paraspinal muscle weakness (head lag) and localized abdominal muscle paralysis causing a bulge (pseudohernia) when the child cries are diagnostic features in many cases, irrespective of the severity. Tendon reflexes of the affected limbs are lost; in others they may be sluggish. The illness usually starts with fever and myalgia, which may last up to a week, followed by the sudden onset of paralysis that progresses to its maximum within 4 days, and is typically asymmetric. Cerebral functions are not altered usually, unless hypoxia occurs. In such cases, drowsiness and occasionally mild muscle rigidity or an extensor plantar response in the unparalyzed limbs may be mistaken for upper motor neuron involvement. These signs disappear with oxygen therapy or assisted ventilation. During the acute phase of illness, the cerebrospinal fluid (CSF) shows predominantly lymphocytic pleocytosis with moderate elevation of protein. Nerve conduction studies show lower motor neuron involvement without sensory neuropathy.

Most children recover from the acute illness, but some 70% continue to have some residual motor weakness, which may vary from mild impairment to complete flaccid paralysis. The permanent loss of motor neurons results in denervation atrophy of the affected muscles. With growth, relative shortening of the limb and deformities such as talipes equinus or equinovarus develop. If the paraspinal muscles are paralyzed, severe scoliosis may develop.

During the acute illness, cranial nerve nuclei of the medulla or higher levels may be involved, manifesting clinically as paralysis of the muscles of deglutition or central paralysis of respiration. This condition is called *bulbar poliomyelitis*. When spinal muscle paralysis and bulbar disease occur together, the term *bulbospinal poliomyelitis* is applied. Occasionally facial (seventh cranial nerve) paralysis may occur, either isolated or in combination with spinal or bulbar poliomyelitis. While the vast majority of poliovirus infections are either asymptomatic or associated with nonspecific febrile illnesses, the case-fatality rate of those who develop poliomyelitis is 2% to 5% and in epidemics as high as 10%. Death is most often due to respiratory paralysis or arrest in children with bulbar poliomyelitis.

Poliomyelitis should be considered in all cases of pure motor paralysis and is usually associated with a normal or slightly elevated value for protein, normal sugar value, and moderate mononuclear pleocytosis in CSF. Early in the illness polymorphonuclear cells may predominate in the CSF, followed by a shift to mononuclear cells. Defects in the ventral horns of the spinal cord can be observed by magnetic resonance imaging (MRI). The MRI lesion corresponds to the innervation pattern of the affected extremity. Electromyography and nerve conduction velocities (NCVs) generally fail to show evidence of a conduction block.

The differential diagnosis includes spinal cord compression, stroke, neuropathy, and Guillain-Barré syndrome (GBS). Spinal cord compression is unlikely in the absence of central involvement in neural imaging. Lack of sensory involvement would exclude neuropathies. For stroke in the setting of meningoencephalitis, flaccid paralysis sometimes occurs, but the classic spasticity of upper motor lesions should follow. In GBS, protein concentration is markedly elevated in the CSF and pleocytosis is mild or absent. Fever is usually absent, and paralysis is usually symmetric and ascending with evidence of conduction block by NCV.

Delayed progression of neuromuscular symptoms (postpolio syndrome) may occur 20 years or longer after the initial paralysis due to poliovirus.<sup>55</sup> Postpolio syndrome is characterized by new muscle weakness associated with dysfunction of surviving motor neurons. The illness is usually associated with deterioration of those nerves involved in reinnervation during recovery from the original poliovirus infection. Inflammation is sometimes present in association with degenerating neurons.<sup>56</sup> It is believed that the life span of these nerves has been shortened by the process of reinnervation. This syndrome is not a form of amyotrophic lateral sclerosis. It does not appear that reactivation or replication of poliovirus is involved, but current data are inconclusive.<sup>57,58</sup>

## Paralytic Myelitis Caused by Other Enteroviruses

A clinical syndrome of AFP may be caused infrequently by certain enteroviruses other than polioviruses. In children, EV71 may cause AFP either sporadically or in small outbreaks. Several other enteroviruses have been found to be associated with AFP on rare occasions. The clinical picture is usually one of a mild disease, occasionally with paralysis of a single muscle such as the deltoid, and often with complete recovery. In a few cases, particularly adults, EV70 has been associated with meningomyelitis and AFP affecting one or more limbs.<sup>59</sup> Although most patients recover completely, some may continue to have residual paralysis, as in poliomyelitis.

## Viral Meningitis

Fever, headache, and nuchal rigidity, often with Brudzinski's sign, are characteristic of meningitis in children and adults. The CSF is usually clear and under normal or mildly to moderately increased pressure and with mild-to-moderate pleocytosis (usual range, 100 to 1000 cells per microliter). Although on the first or second day of illness, CSF cells may be predominantly neutrophils, they are predominantly lymphocytes when evaluated 1 or 2 days later. Enteroviral meningitis usually occurs sporadically while other children are infected

with the same virus without neurologic disease or even asymptomatically. Occasionally it may occur as small outbreaks. Enteroviruses are by far the most frequent cause of viral meningitis in most locations.

In the tropics, enteroviral meningitis occurs almost exclusively in children less than 10 years of age, similarly to poliomyelitis. In temperate regions, it may occur in children or adults, reflecting the delayed age pattern of enterovirus infections in general. The onset is usually sudden, with fever. Sometimes the fever may be biphasic—a short (1 or 2 days) febrile period accompanied by few or no other signs and symptoms and then, after a day or two, the typical features of meningitis. In older children and adults, headache is common, along with photophobia in some. In infants and young children, febrile convulsions may occur at the onset, in which case careful examination is necessary to rule out encephalitis or other CNS disease. Vomiting, anorexia, skin rash, cough, pharyngitis, diarrhea, and myalgia are also frequently present. Before its closure, the anterior fontanel may bulge as a sign of raised intracranial pressure.

Many other viruses may cause viral meningitis, such as mumps, herpes simplex, Epstein-Barr virus, arenavirus, and several arboviruses. The clinical picture and the laboratory findings on CSF examination lead to a diagnosis of aseptic meningitis. Viral isolation in cell culture or suckling mice from CSF is successful only early in the course of illness. Virus isolation and detection by molecular methods are the only definitive agent-specific diagnostic results.

Treatment is essentially supportive, and the course of illness is nearly always benign, usually lasting less than a week. Complete recovery is the rule. Although some data suggest that neurologic, cognitive, or development or language abnormalities may follow enteroviral meningitis in infancy, other studies indicate that the prognosis is more benign.

## Encephalitis

Infection of the brain parenchyma is a relatively rare manifestation of enteroviral infection. The encephalitis may be global or focal. It is probably more common in children than in adults in both tropical and temperate regions. The illness starts with fever and constitutional symptoms. After a few days, confusion, irritability, lethargy, or drowsiness develops and usually progresses rapidly to generalized convulsions and coma. In some children, focal encephalitis is characterized by focal seizures, very much as in herpes simplex virus encephalitis. Other clinical manifestations are usually related to elevated intracranial pressure and to cranial nerve or cerebellar involvement. Occasionally myelitis may also occur, with lower motor neuron paralysis of muscles.

More recently, a syndrome of fatal brain stem encephalitis has been described in several countries of Southeast Asia that is associated with EV71 infection.<sup>60,61</sup> Although sporadic cases of infection with this virus have been described since the virus was first recognized in 1971, the deaths occurred in the context of widespread hand-foot-and-mouth disease (HFMD) outbreaks. The fatal outcome had few clinical predictive symptoms but was specifically associated with young children, mostly less than 2 years of age. The onset of neurologic symptoms was particularly rapid, and death occurred often within 24 hours as a result of cardiopulmonary failure, presumably neurogenic.<sup>62</sup>

The CSF is usually clear with mild, predominantly lymphocytic pleocytosis in the usual range of 5 to 200 cells per microliter. The CSF protein concentration is normal or slightly elevated, and the glucose concentration is normal or slightly decreased. As a rule, CSF culture does not yield an enterovirus. Brain tissue is seldom obtained by biopsy for virus isolation. It is generally believed that herpes simplex virus, several arthropod-transmitted viruses, and enteroviruses are the most common causes of viral encephalitis.

## Acute Myocarditis and Pericarditis and Chronic Sequelae

Acute myocarditis with or without pericarditis caused by several EVs can occur in infants, children, adolescents, and young adults. The most common serotypes implicated with acute myocarditis are the coxsackie B viruses.<sup>63</sup> Myocarditis usually starts with fever and mild symptoms followed after a short interval by palpitations, chest pain, shortness of breath, and congestive cardiac failure. Occasionally, arrhythmia may be the only manifestation. Pericarditis may accompany myocarditis; often a pericardial rub is heard, but occasionally there is frank pericardial effusion. Investigation usually confirms cardiomegaly and electrocardiographic evidence of myocarditis. The case-fatality rate is high enough to warrant caution in predicting prognosis.

Treatment is supportive. Most patients recover; however, sequelae have been recognized, including chronic myocarditis, dilated cardiomyopathy, and chronic relapsing or constrictive pericarditis.<sup>64,65</sup>

## Acute Hemorrhagic Conjunctivitis

Mild conjunctival hyperemia is noted with many EV diseases. However, a severe form of conjunctivitis, usually occurring in rapidly spreading epidemics and characterized by subconjunctival hemorrhage in nearly half the subjects is caused by two enterovirus serotypes. This disease is different from other enteroviral illnesses, having occurred in global pandemics since its introduction around 1969, when both EV70 and CVA24v emerged as causes of acute hemorrhagic conjunctivitis (AHC).<sup>66,67</sup> AHC epidemics have recurred in many regions at periodic intervals, with several years in between. To date they have occurred largely in the tropical and subtropical countries of Asia, Africa, and Latin America. Only sporadic cases or small outbreaks have occurred in temperate climates.

The illness has a sudden onset. The incubation period for these agents is shorter than for other enteroviruses (24 to 72 hours), systemic illness much less common, and conjunctival replication of virus is the rule. Spread is mainly through direct contact, via fingers or fomites. Eye pain, photophobia, excessive lacrimation, and congestion of the conjunctiva are almost always present. In most cases, the ocular discharge is nonpurulent but may be mucoid in severe cases. The characteristic subconjunctival hemorrhage in a proportion of cases in the epidemic is an important diagnostic feature. The disease is usually bilateral. Adults and school-age children are more affected than infants and preschool children, although household spread is efficient regardless of age. After a few days, symptoms abate, but the hemorrhage resolves slowly. Soothing eye drops, such as sterile saline or mild

decongestants, are used to ameliorate the symptoms. Recovery is complete in 5 to 10 days.

During EV70 epidemics, a small proportion of subjects develop acute paralysis of muscle groups of one or more limbs, usually within a few days after the onset of eye disease, resembling poliomyelitis, but in reality a radiculomeningomyelitis.<sup>59</sup> Other than this, the only common complication is secondary bacterial infection.

### **Pleurodynia (Bornholm Disease)**

A distinct illness with mild or high fever of short duration and chest pain located on either side of the sternum or retrosternally may occur sporadically or in outbreaks. The pain is usually intermittent or spasmodic and sometimes excruciating, often exacerbated by deep breathing. Intercostal muscle tenderness and a pleural rub, when present, are important signs distinguishing the illness from myocardial infarction, which is often suspected in adults. The chest radiograph and electrocardiogram are normal. Symptoms usually last for a few days to more than 2 weeks, with occasional relapses. In children severe abdominal pain, apparently arising from the diaphragm, may occur.

This syndrome has primarily been associated with coxsackie B viruses,<sup>68</sup> particularly CVB3 and CVB5, although sporadic cases may be caused by other enteroviruses. Rarely, pleurodynia may be accompanied by another clinical manifestation of enterovirus infection, such as aseptic meningitis, or even myocarditis.

### **Hand-Foot-and-Mouth Disease**

The distinguishing feature of this illness is the vesicular eruption of the hands and feet and in the mouth. The oral lesions, mostly on the buccal mucosa, become shallow ulcers. Coxsackievirus A16 is the most frequent etiologic agent, occasionally causing outbreaks. Other enteroviruses, especially coxsackieviruses A10 and EV 71, may also cause HFMD outbreaks. The etiologic agent can be isolated from the vesicles and from the throat and feces. Occasionally, HFMD may occur with other enterovirus involvement such as meningitis.

### **Herpangina**

This illness is characterized by a typical crop of vesicles on the soft palate, uvula, other parts of the oropharynx, or the tongue. Each vesicle is about 1 to 2 mm in diameter, with a surrounding red areola. It occurs usually only in children younger than 10 years old. Fever and sore throat are the common symptoms. Careful examination of the oropharynx reveals 1 to 10 or 12 discrete lesions, which usually subside without ulcerating.

### **Short Fever with Maculopapular Rash**

Many enteroviruses may cause a short febrile illness with a maculopapular rash resembling rubella or mild measles, particularly in infants and very young children. The distribution of the rash on the face, neck, and chest, and occasionally on the arms and thighs may mimic other well-recognized exanthems. Sometimes there may be mild upper respiratory symptoms, adding to the difficulty of accurate clinical

diagnosis. Outbreaks of enterovirus exanthem have also been called Boston exanthem.

### **Diarrhea**

Mild diarrhea is a common accompanying symptom in many enteroviral diseases. However, occasionally enteroviruses may cause a short diarrheal illness. Although occasional outbreaks of diarrhea without other typical enterovirus symptoms have been attributed to enterovirus infections, these are very uncommon.

### **Neonatal Enterovirus Diseases**

Neonates are more vulnerable to invasive enterovirus diseases than are older children and adults. In the tropics, where most adults are immune to enteroviruses, neonates are protected by maternal antibodies. Therefore, paradoxically, neonatal enteroviral diseases are more common where the general transmission potential is less intense than in the tropics. Infection may occur in utero or, more commonly, perinatally.

Many of the clinical features described previously in relatively distinct and self-limited illness, as well as the more sinister lesions in the CNS or the heart, may cluster together in the sick neonate.<sup>69,70</sup> Such illnesses very much resemble other severe systemic infectious disease such as bacterial septicemia. Thus, the infant may present with lethargy, feeding difficulty, vomiting, tachycardia, dyspnea, cyanosis, jaundice, and diarrhea, with or without fever. Clinical evidence for aseptic meningitis, encephalitis, myocarditis, hepatitis, or pneumonia may be present in any combination. The case-fatality rate is high. Sometimes death may occur rapidly.

### **PATHOGENESIS**

Enteroviruses are cytopathic, and much of the associated disease presumably results from tissue-specific cell destruction. Some disease manifestations, enteroviral exanthems and myocarditis, for example, are thought to result from the host immune response to the infection.<sup>2</sup> The actual mechanisms of virus-induced disease, however, have not been well characterized. Typically, the primary site of infection is the epithelial cells of the respiratory or gastrointestinal tract and in the lymphoid follicles of the small intestine, followed by a viremia that may lead to a secondary site of tissue infection. Secondary infection of the CNS results in aseptic meningitis or, rarely, encephalitis or paralysis. Other tissue-specific infection can result in pleurodynia or myocarditis. Disseminated infection can lead to exanthems, nonspecific myalgias, or severe multiple-organ disease in neonates.

Virus infection is dependent on the presence of specific receptors. Five distinct receptors for different nonpolio enteroviruses have been identified from human cells, two different integrins, decay-accelerating factor (DAF), the "coxsackievirus-adenovirus receptor" (CAR), and intracellular adhesion molecule 1 (ICAM-1). The receptor for poliovirus (PVR; CD155) is a member of the immunoglobulin superfamily. Some enteroviruses are able to use more than one receptor, and other unidentified receptors for this group of viruses may also exist. These host receptors may also contribute to host specificity, although studies comparing receptor homologs in resistant hosts are still in progress. Studies of the virus-receptor

interactions should improve our understanding of the pathogenesis of enteroviral disease and, possibly, help develop prevention or treatment strategies.<sup>71</sup>

Once attached to the host cell, the virions are thought to be transferred into the cell by pinocytosis. Poliovirus is also endocytosed by M cells in the gut, and this may also be true for other enteroviruses. After virus entry into the host cell, the virus genome is released into the cytoplasm where it then functions as a messenger RNA. Translation leads to the synthesis of viral structural proteins, two proteases and the viral replicase. The sites of viral replication are cytoplasmic membranes that are increased during the infection.<sup>72</sup> Along with the newly formed capsid proteins, the replicated genomic RNA is assembled into progeny virus particles, which are released from the cell by cell lysis or apoptosis.<sup>73</sup> A single virion is thus replicated to generate tens of thousands of progeny virions within a few hours.

The sequence of events following virus infection of the host is generalized from experimental infection of polioviruses in chimpanzees and monkeys, partially corroborated by fragmentary data in sick children. After multiplication at and near the primary site of entry, virus reaches the adjacent lymphoid follicles and draining lymph nodes. Viral multiplication may continue at these sites, and virus is shed into the pharyngeal and intestinal lumina for many days to several weeks. Transient viremia occurs, at least in some cases. When such primary viremia disseminates the infection to distant sites, other susceptible organs may become infected. A second amplification resulting from infection and release of virus from these sites may result in a more intense secondary viremia and further widespread dissemination. Disease may manifest following the primary or secondary viremia. Primary viremia starts 1 to 3 days after virus inoculation and lasts for 1 to 5 days. Secondary viremia starts soon thereafter and may also last for a few days. The appearance of virus-neutralizing antibody in blood coincides with, and may be responsible for, cessation of the viremia, although other factors may also limit the viremia period in the absence of antibody.

The exact pathway taken by enteroviruses to reach the CNS is not clearly understood. Viremic spread across the blood-brain barrier or entry via peripheral nerves are two possibilities.<sup>74,75</sup> The relatively broad range of the incubation period (5 to 30 days) suggests that one pathway may operate in some cases and the other pathway may be taken in others. It is possible that the route of viral spread may, at least in part, determine the site of lesions and the consequent nature of disease. It is also possible that the second pathway is only used by poliovirus among the enteroviruses. For reasons that are not clear, there is a predilection to poliovirus infection and neuronal damage in the lumbar enlargement of the spinal cord leading to lower limb paralysis in a majority of cases.

Polioviruses exhibit the greatest neurovirulence among the enteroviruses; all others have varied but lower neurovirulence. Neurotropism and neurovirulence are at least, in part, two genetically determined properties of the virus. The specific neurotropism related to poliomyelitis is correlated with the use of the specific poliovirus receptor by the virus.<sup>76,77</sup> The RNA sequences of neurovirulent and attenuated vaccine strains of polioviruses show only a very limited number of base changes and indirectly suggest viral determinants affecting neurovirulence. Sequence similarities within the 5' noncoding region between polioviruses and other enteroviruses that are

the result of recombination suggest that the potential neurovirulence of some of the other enteroviruses may be greater than previously recognized,<sup>12</sup> or that vaccine attenuation is a distinct process. Regardless, the reason CNS disease is not more common among infected children is not clear.

In myelitis caused by polioviruses, neurons of the anterior horn region are infected. While many cells are killed and removed by neuronophagia, others recover and regain their function. Paralysis is due to damage to many motor neurons. Neuronal recovery is also reflected in the recovery of muscle function. It is not generally appreciated that a large number of scattered neurons may be destroyed without resulting paralysis. Perivascular lymphocytic cuffing and interstitial microglial infiltration are usually also observed.

There is a marked increase in the risk of developing paralysis when intramuscular injections are given during the incubation period.<sup>78</sup> This "provocation poliomyelitis" may be explained by possible enhancement of virus entry into the peripheral nerves via the nerve endings in the injected muscle.<sup>79</sup> In such cases the limb in which the injection was given is significantly more frequently affected by paralysis. In experimental animals, poliovirus injection into the ulnar nerve has consistently caused AFP, clinically closely resembling the human disease.

## IMMUNITY

Infection with enteroviruses elicits a strong humoral immune response. Infection with one serotype provides long-term protection from infection by that serotype but usually little protection from infection by other serotypes. Often this response is heterotypic; that is, infection with one serotype induces an immune response to several other serotypes.<sup>80,81</sup> Young children develop a more homotypic antibody response, whereas older children and adults develop a more heterotypic response. This age difference in the specificity of the antibody response to an enterovirus infection probably reflects exposure to a greater number of serotypes with advancing age. The basis of this heterotypic response is not known, but it may reflect shared epitopes present in multiple serotypes.

Although both humoral and cell-mediated responses occur, the former is probably more important and certainly better investigated and understood. It is not clear what role may be played by cell-mediated immunity in recovery or protection, other than supporting the humoral response. Antibodies are usually detected and quantitated using the property of virus neutralization, by which infectious virus is rendered noninfectious following antibody binding. Virus-binding antibody can be detected and quantitated by enzyme-linked immunoassay (EIA). This method is easily adapted to detecting and measuring class-specific (IgM, IgG, and IgA) antibodies. Although antibody has to bind to the virus for neutralization, only antibodies directed at certain specific surface epitopes will render the virus noninfectious. Antibodies directed at many other non-neutralizing sites are also detected by EIA. While neutralizing antibodies are highly serotype-specific, antibodies detected by EIA are usually more broadly reactive and less specific.

Within 7 to 10 days after primary infection, IgM antibodies appear in the blood, subsequently rise in titer, and persist for up to 3 to 6 months. IgG antibodies appear shortly thereafter, rise in titer over 2 to 3 weeks, and remain at relatively

high levels for a few years; they persist at detectable levels for one or more decades. IgA antibody appears after 2 to 4 weeks, both systemically and at mucosal surfaces. Local immunity, which inhibits reinfection, is due partly to mucosal IgA and partly to serum IgG transudate. Humoral immunity is believed to be the major factor in recovery from and clearance of enterovirus infection, as well as protection from disease upon reinfection or from reinfection itself on re-exposure. In the case of polioviruses, vaccine-induced humoral immunity protects against invasive disease and to a lesser extent against reinfection and amplification. Children with agammaglobulinemia do not develop antibodies; hence, they are highly susceptible to disease and chronic infection with prolonged virus shedding. Despite widespread transmission of wild poliovirus and extensive use of oral poliovirus vaccine (OPV) in areas with high incidence of HIV infection, surveillance data do not suggest that persons with HIV infection or AIDS are at higher risk of poliomyelitis or prolonged excretion of polioviruses. One study found that HIV-infected children were more likely than HIV-negative children to shed enteroviruses; however, two other studies in Africa did not detect prolonged excretion of poliovirus among children or adults with HIV infection or AIDS.<sup>82-84</sup>

Like other gastrointestinal infections, the local immunity is neither absolute nor long lasting. Reinfections do occur, but the duration of viral shedding is shortened. There is no risk of disease in reinfection, since systemic immunity prevents viral dissemination, even long after primary infection. In other words, the risk of invasive infection and disease occurs only with the primary infection. However, such reinfections can contribute to continued circulation of polioviruses in spite of high immunization coverage in regions with high force of transmission.

## DIAGNOSIS

The key to laboratory confirmation of enterovirus infection is the collection of appropriate clinical specimens for direct detection by molecular methods, virus isolation, or serologic studies.<sup>85</sup> Enterovirus infection cannot be inferred from the clinical syndrome alone, since many other infectious agents can cause similar illness. In the case of poliovirus, isolation also makes it possible to determine whether the virus is wild or vaccine-related.<sup>86</sup> In areas considered to be free of wild poliovirus, this information may be important to public health officials, who must decide whether intervention is needed to prevent further cases of poliomyelitis.

Enterovirus isolation is accomplished by inoculation of appropriate specimens onto susceptible cultured cells. The best specimens for isolation of virus, in order of sensitivity for detection, are stool specimens or rectal swabs, throat swabs or washings, and CSF. Fecal specimens should always be obtained, since virus is excreted longest and in the highest titer from the intestinal tract. Throat swabs or washings and CSF are most likely to yield virus isolates if they are obtained early in the acute phase of the illness. For cases of acute hemorrhagic conjunctivitis, the best specimens, in order of sensitivity, are conjunctival swabs and tears. The virus is detected in cell culture by its cytopathic effect and classically identified as a specific enterovirus by neutralization with type-specific antisera,<sup>87</sup> but serotyping remains a time-consuming and expensive procedure.<sup>85</sup>

For cases of poliomyelitis, WHO has established a standard procedure for investigation, and it is applied to all cases of AFP, not only suspected poliomyelitis. Most countries of the world have adopted this standard approach, referred to as AFP surveillance.<sup>88</sup> The laboratory procedures are extensively documented and implemented in all 145 laboratories that make up the Global Poliovirus Laboratory Network. Stool specimens from any child can be sent to one of these laboratories to be tested for the presence of poliovirus. In addition, this information is then shared immediately with public health officials for an appropriate response (see later discussion).

The use of the polymerase chain reaction (PCR) to detect enterovirus genomes in cell culture, clinical specimens, and tissues promises to significantly improve the detection of enteroviruses.<sup>89,90</sup> This technique is more rapid than isolation and has the potential for providing diagnostic answers in a timely way for clinical patient management. Molecular serotyping systems offer many advantages and may eventually supplant antigenic typing as global stocks of serotype-specific antisera are depleted.<sup>91</sup> Methods have been developed using the PCR assay for rapid detection and characterization of polioviruses, including determination of the virus serotype.<sup>92</sup> Nucleic acid probes, PCR, enzyme-linked immunosorbent assay (ELISA), and monoclonal antibodies can be employed to determine whether the isolate is vaccine-derived or wild poliovirus. The different methods have different sensitivities and specificities for the different strains of viruses.<sup>86</sup>

Serologic studies can be used in certain circumstances for detecting infection. Classically, infection has been demonstrated by a rise in titers of neutralizing antibody between acute and convalescent serum pairs. Poliovirus infection may occasionally be confirmed by demonstrating a rise in titers of neutralizing antibody to one of the poliovirus serotypes, but because of widespread use of vaccine this is often compromised. Enzyme immunoassays have been developed, such as those to detect CVB-specific IgM antibodies.<sup>93</sup> In most cases, the IgM antibody tests are not serotype specific. Depending on the configuration and sensitivity of the test, from 10% to nearly 70% of serum samples show a heterotypic response due to other enterovirus infections. A positive result with this method indicates recent enteroviral infection, although with IgM assays the infecting serotype may not be the same one determined by the assay. In general, serology is more valuable as an epidemiologic tool than for clinical diagnosis.

A general diagnostic caveat, however, is shared among enteroviruses and other ubiquitous pathogens. Since enterovirus infections are quite common, especially in childhood, and since most infections are noninvasive and prolonged, the detected enterovirus infection need not be the cause of the illness under investigation. It is an issue of probabilities. If the clinical syndrome is already known to be associated with the detected agent, then infection is taken as reasonable evidence of causation. If the presence of the agent is found in diseased tissue or a relevant body fluid (such as CSF), that constitutes concrete evidence of invasion, hence causation.

## TREATMENT

Since no antiviral therapy is presently available for enterovirus infections, treatment is directed toward alleviating symptoms. Drugs have been identified that exhibit antiviral activity against several enteroviruses including poliovirus in

tissue culture and experimental animals.<sup>94,95</sup> These drugs, however, have not completed clinical trials. Interferon has been proposed for treatment of acute hemorrhagic conjunctivitis, but this awaits further evaluation.

Treatment of acute poliomyelitis consists principally of supportive therapy and reduced physical activity. Mechanical ventilation is sometimes required in severe cases. Although specific antiviral treatment for poliovirus has been pursued for many years, there is no currently available drug treatment for polioviral infections in clinical use. Several classes of compounds have been identified that exhibit antiviral activity against poliovirus in cell culture and experimental animals.

In patients with agammaglobulinemia, chronic enterovirus infections have been treated with  $\gamma$ -globulin, and in some cases this has controlled the infection. Use of  $\gamma$ -globulin in other clinical illness has not been systematically evaluated.

## PREVENTION AND CONTROL

No vaccines are available for nonpolio enteroviruses. General preventive measures include enteric precautions and good personal hygiene. Enteroviruses can be a cause of nosocomial infection. Life-threatening infection is most common in newborns, although persons with compromised immune systems are also at higher risk. Hospital staff can inadvertently carry the virus between patients or become infected themselves and spread the virus. Patients with suspected enterovirus infection should be managed with enteric precautions. Patients and staff can be cohorted during outbreaks. During several newborn outbreaks in hospitals, neonatal nurseries were closed to new admissions.

### Prevention of Disease by Immunization

By the 1950s, two different approaches to the prevention of poliomyelitis by vaccination were developed. The first successful polio vaccine, the inactivated polio vaccine (IPV), was produced by Salk and Youngner in 1954 by formaldehyde inactivation of cell culture-propagated virus.<sup>96</sup> This vaccine was completely noninfectious, yet following injection elicited an immune response that was protective against paralytic disease. During the same period, many laboratories sought to produce live, attenuated polio vaccines. The OPV strains of Sabin were licensed in 1961 and widespread mass immunization campaigns in the United States began in 1962.<sup>97</sup> Both IPV and OPV contain three components, one for each immunologically distinct serotype of poliovirus.

The vast majority of countries use OPV exclusively, and a few countries use only IPV. A limited number use both in sequence. Recommended vaccination schedules vary among countries, and debate continues about the relative merits of the two. The immunogenic and protective efficacies of OPV show geographic variation, and multiple doses are often required in some of the least developed countries of the tropics. Whereas in North America or Europe, almost all infants seroconvert to all three types of polioviruses with three doses of OPV, in tropical developing countries, 72% and 65% of infants develop antibodies to types 1 and 3 polioviruses, respectively, in response to three doses of OPV, and additional doses are necessary to get equivalent seroconversion rates.<sup>98,99</sup>

Nevertheless, polio has been eliminated from the Americas and the Western Pacific region, as well as tropical countries in South Asia, such as Bangladesh and Indonesia, using OPV exclusively. The reason for low seroconversion rates is not fully known, although recent studies strongly implicate the presence of diarrheal disease at the time of OPV administration as an important factor.

While OPV is an extremely safe vaccine, it has been found to induce paralytic myelitis in a few instances. In primary vaccinees, vaccine virus-associated paralysis occurs at a rate of less than 1 in 500,000. The probability of vaccine-induced paralysis is higher in hypogammaglobulinemic children given OPV and in (nonimmune) adults in close contact with a recently immunized infant. In tropical regions, when the risk of poliomyelitis due to wild polioviruses was 1 in 200 to 1000, the paralytic risk of OPV was not an important concern.

The contemporary IPV is highly immunogenic, and primary immunization consists of a minimum of two doses 8 weeks apart or an optimum of three doses, preferably at 8-week intervals. When given as two doses, the first dose should be at or after 8 weeks of age; the three-dose regimen may start at 6 weeks of age or thereafter. The effect of age and dose interval on seroconversion is under active investigation. A booster dose is recommended during the second year of life and around 5 years of age to achieve a total of 4 doses, and this should suffice for long-term protection. Several IPV-containing combined vaccines are currently available to avoid separate injections.

### Polio Eradication

Poliomyelitis is targeted for global eradication by the year 2005 with remarkable success in all regions of the world. The aim is to terminate the transmission of polioviruses and thereby protect all infants and children from poliomyelitis, rather than protect each child by immunization. The eradication goal is attainable because humans are the only known reservoir for poliovirus. The current global eradication program launched by WHO relies exclusively on OPV for mass vaccination. WHO recommends for developing countries that three routine doses of OPV be given at 6, 10, and 14 weeks of age and an additional dose at birth in endemic regions where exposure of very young infants to wild virus can be expected. To achieve high vaccine coverage in all regions of the world, the Poliovirus Eradication Initiative also relies on supplemental immunization campaigns and aggressive investigation of all suspected cases of AFP to identify wild poliovirus circulation. To ensure that no case of poliomyelitis is missed, every case of AFP in every location in every country must be detected through clinical surveillance and investigated virologically. Two stool samples should be collected on consecutive days, within 2 weeks after the onset of paralysis, and processed for virus isolation.

At least five poliomyelitis outbreaks have been associated with circulating vaccine-derived polioviruses (cVDPV): on the island of Hispaniola in the Americas in 2000–2001, in the Philippines in 2001, in Madagascar in 2002, in China in 2004, and in Egypt from at least 1988 to 1993.<sup>100</sup> The outbreak strains were unusual because their capsid sequences (encoding antigenic properties) were derived from OPV. These viruses had recovered the capacity to cause paralytic

poliomyelitis in humans and to be transmitted efficiently among human populations.<sup>101</sup> Intense investigations suggest that circulation of vaccine-derived virus is a rare event, occurring only in populations with low immunization rates and high population densities. The recent discovery of cVDPVs has created urgency in planning a comprehensive posteradication immunization strategy and emphasizes the fact that risk of polio will not be eliminated until OPV vaccination stops. As a consequence, the eradication effort will need to address issues of future vaccination policy, the containment of laboratory and vaccine production strains, and a coordinated strategy to achieve the cessation of OPV immunization as vital parts of the eradication effort following the successful elimination of wild virus circulation.<sup>102</sup>

## Rotavirus Infections

MARIA C. JAIMES  
JUANITA ANGEL  
MANUEL A. FRANCO  
HARRY B. GREENBERG

### INTRODUCTION

Rotaviruses are the most important cause of severe dehydrating diarrhea in young children in both developed and less developed countries (Box 61-1). In tropical countries (mostly developing countries), rotavirus (RV) infection has several unique characteristics. First, it is a major public health problem, responsible for approximately 1200 deaths in children each day.<sup>1</sup> This presumably occurs because of inadequate access to timely rehydration therapy. Second, in countries within 10 degrees of the equator, rotavirus infection occurs throughout the year, as opposed to countries with more temperate climates where it presents as a seasonal disease, occurring from late fall to early spring.<sup>2</sup> An explanation for this observation is not available. Third, in tropical countries simultaneous infections with multiple RVs is not uncommon, children become infected with RVs at a somewhat earlier age, and the serotypes of the RV strains circulating in tropical settings seem to differ to some degree from what is seen in North America, Western Europe, Japan, and Australia.<sup>3,4</sup>

### AGENTS

Rotaviruses belong to the family Reoviridae. Viruses in this family are icosahedral, nonenveloped, with a segmented double-stranded RNA genome and a multiple-layered protein coat.<sup>5</sup>

Rotaviruses are classified into groups (A through G), depending on the presence of cross-reactive antigenic epitopes and on the overall genetic similarity of their genomes. This chapter focuses on the most thoroughly studied group of RVs, group A, which are the principal pathogen of humans and many other species. Group B and C RVs also infect humans and animals, whereas groups D through G have only been documented in animals. The group B RVs have been associated with annual epidemics of diarrhea in adult humans in China<sup>6</sup> and have been detected sporadically in adults and children in India.<sup>7</sup> Group C RVs have been detected occasionally in diarrheal samples from children worldwide, and sero-epidemiological studies show that infection with this virus can be quite high (up to 50%) in children older than 3 years and adults.<sup>8</sup>

Detailed structural analysis of the viral particle has been performed by cryoelectron microscopy and several viral proteins

have been crystallized.<sup>5</sup> The complete 1000 Å viral particles consist of three protein layers with spike structures extending beyond the outer layer. Each particle has 11 RNA segments surrounded by the innermost protein layer. Each RNA segment is monocistronic with the possible exception of genes 9 and 11.<sup>5</sup> The gene coding assignments and many of the properties of the 11 genome segments of RV have been extensively studied. The virus has eight structural proteins designated by the prefix VP and five nonstructural proteins designated by the prefix NSP. The outer viral layer is composed of a major structural glycoprotein, VP7, and a spike protein, VP4. The latter protein is cleaved *in vivo* by trypsin into VP5 and VP8, a process that greatly enhances infectivity *in vitro* and *in vivo*. The middle viral layer is composed of VP6 and the inner layer is composed of VP2. On the inner side of VP2, VP1, the viral polymerase, and VP3, the guanylyl transferase, are associated with the viral RNA. It has been shown that antibodies against VP7 and VP4 can neutralize RV growth *in vitro*, and the presence of these neutralizing antibodies has been used to evaluate the effectiveness of vaccination strategies. This finding has led to the further classification of RVs into G (glycoprotein, VP7) and P (protease-sensitive, VP4) serotypes.

Viral replication appears to be generally restricted *in vivo* to the enterocytes on the tips of intestinal villi, except in immunodeficient children, in whom infection of the liver and kidney has also been documented.<sup>9</sup> Recent studies, however, appear to indicate that viremia is more common than previously believed, which may signify that replication is more widespread than previously imagined.<sup>10</sup> *In vivo* and *in vitro*

### Box 61-1 Key Features of Rotaviruses

#### **Virus**

Icosahedral, nonenveloped, with triple-layered protein coat  
Genome consists of 11 RNA segments  
Purified rotavirus RNA is not infectious  
Gene reassortment during mixed viral infections

#### **Epidemiology and Seasonality**

Principal cause of severe dehydrating diarrhea in infants worldwide  
Causes 352,000 to 592,000 infant deaths annually in developing countries  
Year-round infection in countries within 10 degrees of the equator  
Winter peaks in all other regions of the world  
Important host range restriction

#### **Disease**

Viral infection mostly limited to the enterocyte  
Diarrhea affects principally children age 2 to 24 months  
Asymptomatic infection and reinfection common  
Diagnosis and treatment  
Rapid diagnosis by viral antigen detection in stool by solid phase immunoassay  
Treatment is supportive, aimed at preventing dehydration  
Jennerian and human attenuated vaccines of acceptable efficacy should be available in the near future

Data modified from Kapikian AZ, Hoshino Y, Chanock RM: Rotaviruses. In Fields BN, Knipe DM, Howley PM (eds): *Fields Virology*, vol. 2. Philadelphia, Lippincott Williams & Wilkins, 2001, p 1787.

viral attachment to the host cell is mediated primarily by VP4.<sup>5</sup> The process of entry of the virus into the cell is not completely elucidated and is preceded by interaction with several putative binding and postbinding receptors.<sup>11</sup> Replication occurs in the cell cytoplasm following partial uncoating of parental viral particles. The cellular genes activated by viral infection have been studied using microarrays.<sup>5</sup> Assembly of new viral particles is a multistep process in which unique transient enveloped particles are present inside the endoplasmic reticulum of the infected cell. Mature virions, without an envelope, can be liberated from infected live cells by exocytosis or after cell lysis.<sup>5</sup>

Transfected purified genomic RV RNA is not infectious. This feature has hampered molecular manipulation of the RV genome.<sup>5</sup> The RV genome, because of its segmented nature, is capable of undergoing gene reassortment at high frequency during mixed viral infections. The ability to isolate genetic reassortants has been exploited to make gene coding assignments for the virus. In addition, genetic reassortants have been used to develop "modified jennerian" vaccine candidates in which attenuated animal viruses carry one or two human RV genes encoding the RV surface proteins.

## EPIDEMIOLOGY

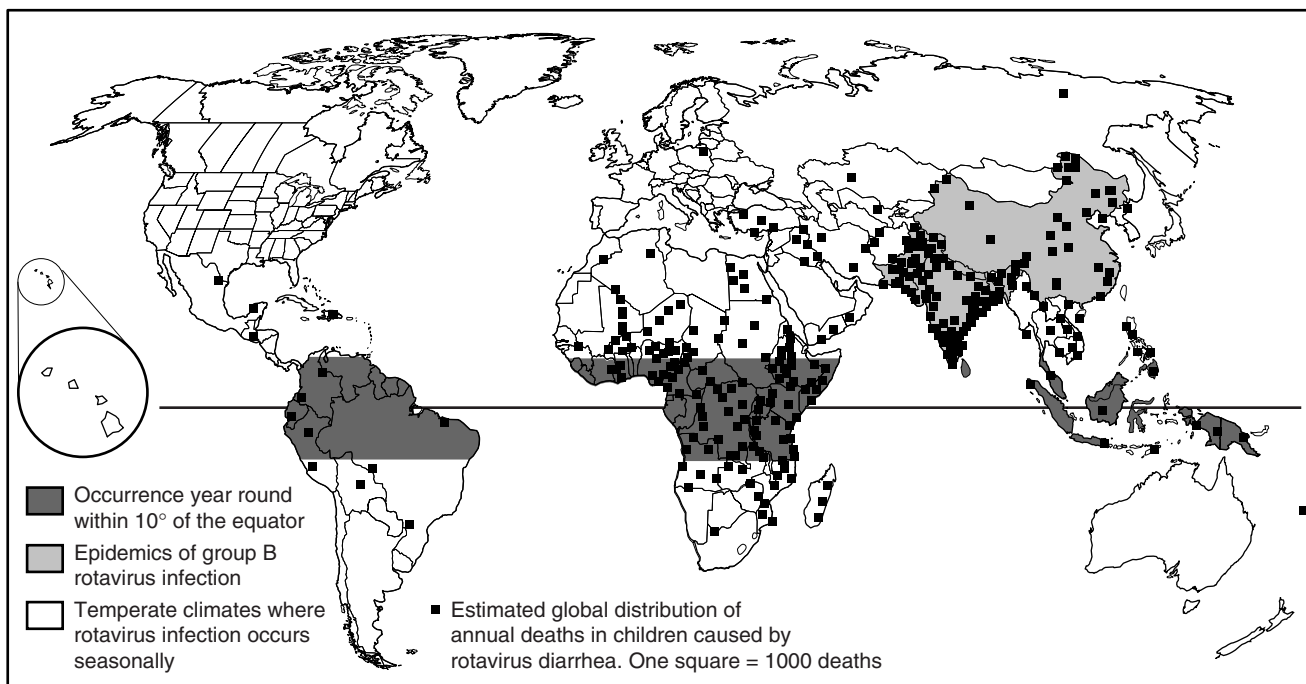

Diarrhea accounts for 2.5 million deaths per year in children younger than 5 years old in developing countries,<sup>12</sup> and of these RV is estimated to be responsible for 14% to 20% (352,000 to 592,000 deaths annually).<sup>1</sup> Although the mortality caused by RV is very low in developed countries, the incidence of rotaviral disease is similar in children in both developed and developing countries, suggesting that common public health measures will not replace the need for an effective vaccine.<sup>1</sup> Moreover, in developed countries RV is still a very important public health problem and has an enormous health cost impact.<sup>13</sup> In the United States, for example, in children

aged 1 month through 4 years, 13.5% of hospitalizations are associated with diarrhea, and RV accounts for 16.5% to 30% of cases.<sup>14</sup>

In the temperate zones of the world, rotaviral infection occurs primarily during epidemic peaks in the cooler months of the year.<sup>2</sup> This pattern is not seen in countries within 10 degrees of the equator, where infection occurs in an endemic fashion year-round.<sup>2</sup> In the United States, a yearly wave of rotaviral illness spreads throughout the country, originating in the southwest in November and ending in the northeast in March.<sup>15</sup> A similar pattern of distribution has been reported in Europe.<sup>16</sup> A clear explanation has not been provided for this interesting phenomenon.

Rotaviruses are usually transmitted by the fecal-oral route, but indirect evidence suggests that they may also be transmitted by the respiratory route.<sup>15</sup> A study has shown that feces from asymptomatic adults may provide a vehicle for the transmission of RV.<sup>17</sup> Water-borne outbreaks of RV are probably rare due to the relative instability of RV at high relative humidity.<sup>5</sup> Food-borne outbreaks are also rare, although it has been reported that oyster and mussel samples can be heavily contaminated by RV.<sup>18</sup> Although animal and human group A RVs can reassort in vitro, substantial host range restriction barriers inhibit widespread intraspecies transmission and reassortment in vivo. However, some studies have shown that strains isolated from India, Brazil, and Malawi are reassortants between human and animal strains.<sup>3,19,20</sup>

Worldwide, most human infections are caused by RV group A of four serotypes: P[8]G1 is by far the most common (53% of strains), followed by P[8]G3, P[4]G2, and P[8]G4.<sup>21,22</sup> Nonetheless, in the past 10 years G9 has been recognized as a very important emerging serotype, being detected at significant rates in developing and developed countries.<sup>21,23-25</sup> Other unusual strains currently circulate and can arise sporadically in both developed and developing countries, but

especially in the latter<sup>23,26</sup>. In India, strains of genotype P[6] account for 43% of typeable strains<sup>21</sup>; in Brazil, G5 strains are commonly found in children with diarrhea<sup>21</sup>; and in The Netherlands, a major outbreak of diarrhea among neonates was reported to be due to a P[6],G9 virus.<sup>26</sup> Whether these unusual serotypes will emerge as major causes of disease in large areas of the world remains to be determined. Also, although generally most RV infections are caused by only one virus, the number of mixed infections reported has increased, mostly in developing countries.<sup>24,25</sup>

## DISEASE

The pathophysiology of human RV-induced diarrhea has not been fully elucidated.<sup>27</sup> The pathologic changes in the intestines of children with severe RV infection include shortening and atrophy of the villi, mononuclear infiltration in the lamina propria, and distention of the cisternae of the endoplasmic reticulum.<sup>28</sup> A direct relationship between the extent of intestinal histopathology and disease has not been demonstrated either in humans<sup>29</sup> or in mice.<sup>5</sup> This discrepancy between histopathology and disease may be explained by the fact that RV can cause diarrhea by multiple mechanisms at different times after infection.<sup>27</sup> During the initial phases of the disease, secretory,<sup>30,31</sup> altered intestinal motility and altered paracellular permeability components may all play important roles in the pathophysiology of diarrhea. Late in the disease a malabsorption component due to destruction of enterocytes or defective turnover of microvillar membrane disaccharidases may cause an osmotic diarrhea.<sup>27</sup> Rotaviral NSP4 was the first viral enterotoxin<sup>30</sup> described and has been proposed to mediate (at least partially) all of the mechanisms mentioned previously. It has been postulated that viral infection (NSP4 being implicated or not) induces secretory diarrhea and probably increases intestinal motility by stimulating the enteric nervous system.<sup>31,32</sup> Whether the toxic effect of NSP4 is physiologically and clinically relevant in children or other animals besides mice remains to be determined.

The factors that determine viral virulence seem to be multiple and depend on both viral and host elements: Studies in mice using reassortants between a murine virus and a simian virus concluded that NSP1 was important in determining viral virulence, whereas VP4 and VP7 were not.<sup>5</sup> Studies in pigs with virus reassortants have implicated VP4, VP3, VP7, and NSP4 but not NSP1 in affecting viral virulence.<sup>5</sup> In a study in Mexico, the severity of RV-associated diarrhea was related to different P serotypes rather than to G serotypes.<sup>33</sup>

The peak incidence of rotaviral illness in children occurs between 2 months and 2 years of age and occurs at a younger age in developing than in developed countries.<sup>34</sup> Rotavirus infection is frequently asymptomatic in neonates, suggesting infection with specific attenuated strains during the neonatal period and/or protective maternal immune effects.<sup>35,36</sup> In adults, infection is generally asymptomatic, and disease is seen occasionally in the elderly and in personnel who take care of sick children.<sup>37,38</sup>

The clinical features of RV illness are not distinguishable from other enteric infections and do not permit a diagnosis based only on physical examination and history.<sup>5</sup> Typically, RV-induced diarrhea is watery, lasts for approximately 5 days, is preceded by the sudden onset of vomiting, and is frequently

accompanied by fever and dehydration.<sup>39</sup> The incubation period of RV has been estimated to be less than 48 hours. Viral excretion in feces lasts 10 days in the majority of children and up to 57 days in small subgroups.<sup>40</sup>

Although in all species examined to date, RV infection appears to be highly restricted to the mature villus tip cells of the small intestine, there is increasing evidence of extra-intestinal spread of the virus, and viremia, in humans and other species.<sup>9,10</sup> The role of extraintestinal RV spread, especially in fatal cases, is unclear.<sup>41</sup> Seizures have been reported in association with RV infection and the virus has been detected in cerebrospinal fluid samples by polymerase chain reaction (PCR).<sup>42</sup> Electrolyte abnormalities and fever associated with infection may also explain some of the seizures, and a firm conclusion concerning the mechanism of seizures cannot currently be drawn.

Many innate mechanisms participate in the host's defense against RV: Age-dependent gastric inactivation of heterologous RV has been shown in mice<sup>43</sup> and has been invoked as one of the factors that determine the age restriction of RV-induced diarrhea in mice. Intestinal mucins, certain cytokines, and chemokines have also been proposed as innate intestinal factors that may play a role in modulating RV infection.<sup>5</sup>

The immune system has been shown to be crucial for eliminating RV infection, since immunodeficient mice and children do not resolve primary infection and become chronically infected.<sup>9</sup> Studies in mice have shown that both antibody and cytotoxic T cells can mediate viral clearance and protection from RV reinfection. Cytotoxic T lymphocytes are probably the initial effector mechanism that mediates viral clearance, whereas antibodies are the principal mechanism of protection from reinfection.<sup>5</sup>

The observation that children infected with RV as neonates were later protected against severe RV disease as well as the fact that in animal models primary infection protects against reinfection indicated that vaccination against RV was feasible.<sup>35</sup> It has been shown that natural RV infection can protect against reinfection. Recurrent episodes of RV disease are less severe than the first episode: One episode of RV infection had a protective efficacy of 77% against RV-induced diarrhea and two RV infections, either symptomatic or asymptomatic, completely protected against moderate to severe disease.<sup>44</sup>

One explanation for recurrent RV infection after primary infection is that protection from reinfection is mediated by intestinal RV-specific IgA, which is not long-lasting.<sup>45</sup> Secondary infections will generally boost the fecal IgA response and in many but not all children induce protective fecal anti-RV IgA levels.<sup>45</sup> A second explanation for recurrent illness is that protective antibodies are primarily directed at serotype-specific regions on the rotaviral proteins VP4 and VP7, the two proteins of the outer viral layer.<sup>5</sup> According to this hypothesis, people become reinfected if they encounter a second RV with VP4 or VP7 proteins of different serotypes from the virus that caused their first infection. This possibility has been supported by some animal and clinical studies<sup>46,47</sup> but not by others.<sup>48</sup>

Based on the hypothesis that protective immunity is specific for the VP7 or VP4 serotypes, a major effort has been devoted to characterizing the serologic variability of the two outer RV proteins. However, protective efficacy following human and

murine vaccination has not been strictly dependent on the serotype of the vaccine strain, nor has it correlated well with the titer of serotype-specific serum antibody,<sup>48</sup> and currently there is no precise and reliable marker of protection induced by vaccination. These observations suggest that local antibody levels may be the critical determinant of protection or that antibody levels to non-serotype-specific regions of VP4, VP7, or other proteins may play an important role in immunity. It is interesting to note that in mice, nonneutralizing antibodies to VP6 (an antigenically conserved protein making up the middle layer of the virion) can also protect against RV reinfection,<sup>49</sup> probably by inhibiting intracellular viral transcription. In addition, suckling pups nursed by dams vaccinated with an NSP4-derived peptide can be partially protected from heterologous RV diarrhea.<sup>30</sup>

## DIAGNOSIS

Diagnosis of RV infection in the clinical setting is not strictly essential when diarrhea is of mild or moderate intensity. During the RV "season" in developed countries, well over 50% of the moderate to severe diarrheal episodes in young children will be due to RV. In tropical countries, because of the presence of other enteric pathogens and the absence of seasonal occurrence of rotaviral disease, it is more difficult, without a diagnostic assay, to determine which diarrheal episode is caused by RV. There are several sensitive, specific, and rapid diagnostic assays for RV; probably the simplest and fastest are solid phase immunoassays that detect RV antigen in stool samples.<sup>50</sup> A second simple and inexpensive method of detecting and characterizing RVs is silver staining of electrophoretically separated viral RNA extracted from stool samples. This technique (used as a component of molecular epidemiological studies of RVs) has the disadvantage that very similar electrophoretotypes can correspond to very different serotypes.<sup>51</sup> Tissue culture of human RVs has also become a relatively efficient way to identify RVs since RVs grow well in tissue culture when trypsin is added to the culture medium.<sup>5</sup> However, this detection technique is time-consuming and, like electron microscopy, requires specialized expensive equipment and/or reagents. Finally, the use of PCR has increased the sensitivity of assays for detecting RV and has permitted typing of viruses by gene sequence without the laborious process of culturing viruses or the use of less sensitive monoclonal antibody-based typing assays.<sup>52</sup> Microarray methods have been proposed for genotyping the virus.<sup>53</sup>

## TREATMENT AND PROGNOSIS

An excellent review on the treatment of gastroenteritis in children has been performed by a Centers for Disease Control and Prevention team<sup>54</sup> and is available at <http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5216a1.htm>. The recommendations of the American Academy of Pediatrics, which include a useful management algorithm, are available at <http://www.aap.org/policy/gastro.htm>.

Because RV disease resolves within 1 or 2 weeks without treatment, the basic therapeutic goal is to prevent dehydration. The oral hydration solution until recently recommended by the World Health Organization (WHO) was derived from the formula initially created to treat secretory cholera diarrhea

and thus had a high sodium concentration and an osmolarity of 331 mmol/L. After a detailed analysis that indicated that the high sodium concentration formula was associated with an increased incidence of transient, asymptomatic hypernatremia, and that rehydration formulas with reduced osmolarity (245 mmol/L) were equally as effective as those with high osmolarity for the treatment of children with cholera diarrhea, WHO changed its recommendation to a lower osmolarity ORS for the general treatment of dehydration.

After rehydration, rapid age-appropriate refeeding is recommended.<sup>54</sup> Rotavirus disease has been shown to induce self-limited intestinal lactase deficiency.<sup>55</sup> Nevertheless, many studies indicate that withholding lactose-containing products, particularly maternal milk, is not warranted.<sup>54,56</sup>

Several studies have indicated that passive oral immunotherapy can shorten the duration of RV infection in animals and humans.<sup>57</sup> This strategy will probably only be economically feasible for special cases, such as the treatment and prevention of RV infection in immunodeficient patients<sup>58</sup> or low-birth-weight infants in whom the newer preparations of antirotaviral immunoglobulins (bovine colostrum and egg yolk immunoglobulins) have not been tested.<sup>59</sup> Recent studies (including a large multicenter European study<sup>60</sup> and a meta-analysis<sup>61</sup>) suggest that *Lactobacillus* (the bacteria present in yogurt) is safe and effective as a treatment for children with acute infectious diarrhea. However, the potential exists for great variability among different preparations of lactobacilli and a general recommendation on their use has not been issued.<sup>54</sup> Although several studies in developing countries have shown that zinc supplementation is useful for the treatment and prevention of diarrhea,<sup>62</sup> further studies are needed to determine if this is the case for nourished children from developed countries. No pharmacological treatment of RV diarrhea is recommended: Racecadotril, an enkephalinase inhibitor that acts on the enteric nervous system, has been shown to be useful as an adjunct to treat RV diarrhea.<sup>63</sup> Ondansetron, a serotonin antagonist, was effective in reducing the emesis from gastroenteritis during the phase of oral rehydration.<sup>64</sup> More studies are needed before these preparations can be recommended for treatment of RV diarrhea.

Acute or chronic complications of RV disease other than dehydration are very rare. Malnutrition, low birth weight, and prematurity are all predisposing factors for the severe, life-threatening dehydration associated with RV disease.<sup>65,66</sup> In developing countries, diarrhea is directly related to linear growth retardation during childhood, a determinant of short stature, and impaired capacities in adults.<sup>67</sup> Associations of RV infection with necrotizing enterocolitis, hemorrhagic gastroenteritis of neonates, and pneumatosis intestinalis in infancy have been reported, but a causal relationship has not been established.<sup>5</sup> HIV-infected children do not seem to be more susceptible to RV, and it will probably be safe to give them the live RV vaccines currently being developed.<sup>20</sup> Although several reports have suggested that group A and C RVs may be implicated in extrahepatic biliary atresia of children, evidence suggests that this is not the case.<sup>68</sup>

Soon after the discovery of RVs, the feasibility of a RV vaccine was established.<sup>69</sup> Studies of the cost-effectiveness of a RV vaccine have clearly established the potential usefulness of this approach.<sup>13</sup> Since RV reinfection occurs even after natural infection, the primary aim of anti-RV vaccination strategies is

to prevent severe RV disease rather than prevent RV infection or mild illness. Based on the observation that animal RVs appear to be substantially restricted for growth, pathogenicity, and transmission in humans (host range restriction), the most studied strategy for vaccination of children has been a jennerian or modified jennerian approach using bovine or simian viruses or reassortants as vaccines. In some cases of strict jennerian vaccine failure, the vaccine and the wild-type human strain did not share G serotype specificities.<sup>46</sup> Therefore, the jennerian strategy was modified to include animal virus reassortants that contained the four genes encoding the most common VP7 (G) serotypes. A vaccine of this type, the quadrivalent rhesus vaccine (RotaShield), was the first licensed for use in the United States and showed efficacy against moderate to severe diarrhea in the 70% to 90% range. This vaccine was subsequently withdrawn from the market because of its association with intussusception within the first 1 or 2 weeks following vaccination.<sup>70</sup> However, the impact of this RV vaccine on the total attributable risk of intussusception remains highly controversial.<sup>70,71</sup> Nonetheless, it seems unlikely that this vaccine will ever be reconsidered for widespread use in the United States. The RotaShield experience did show that this oral vaccine could be administered concurrently with oral poliovirus and breast-feeding and that an oral vaccine could greatly reduce severe RV disease.<sup>72,73</sup>

The jennerian vaccine approach is currently being pursued in China, where an attenuated lamb RV vaccine has been licensed since 2000.<sup>74</sup> A modified jennerian pentavalent vaccine made of bovine virus reassortants containing human G1, G2, G3, G4 (VP7), and P[8] (VP4) is being studied in a large, multicenter trial.<sup>75</sup> A challenge for this vaccine and perhaps other formulations is the increasing number of pathogenic strains with different G serotypes emerging worldwide. Another approach under investigation is based on the excellent protection induced by natural human primary RV infection<sup>35,44,76</sup>: Two different tissue culture-adapted human viruses are being tested as vaccine candidates. An early phase II trial with the neonatal strain RV3 (P[6]G3)<sup>77</sup> showed rather modest immunogenicity and protective efficacy. Better immunogenicity and protective efficacy have been obtained with the 89-12 (P[8]G1) vaccine candidate currently being tested in a large worldwide trial.<sup>78</sup> It remains to be demonstrated, however, whether a vaccine based on a single human strain is able to induce broad immune responses across commonly and newly circulating serotypes. Protection rates provided by the human 89-12 and bovine pentavalent vaccine have varied from 70% to 80% against any RV disease to 90% and 100% against severe gastroenteritis and are similar to protection rates afforded by the discontinued tetravalent rhesus vaccine.<sup>75,76,79</sup>

Promising strategies to improve vaccine efficacy include vaccination with recombinant virus-like particles,<sup>80</sup> microencapsulating the heterologous RVs to improve their immunogenicity after oral administration,<sup>81</sup> or administering recombinant viral proteins produced in vegetables.<sup>82</sup> Based on the observation that maternally derived milk antibodies can protect animals against infection by RV, several investigators have also advocated immunization of pregnant women with RV as a strategy to protect the newborn against RV diarrhea.<sup>83</sup> This strategy is controversial because milk antibodies in humans seem to have a low protective efficacy against RV infection.<sup>84</sup>

Because of the high excretion rate and very efficient spread of RVs, it is unlikely that disease transmission will be affected substantially by traditional hygiene and public health interventions. Decontamination of surfaces thought to be contaminated with RV should be done with care because RVs have been shown to be highly resistant to many commonly used disinfectants.<sup>85</sup> A spray composed of 0.1% *o*-phenylphenol and 79% ethanol has been shown to be highly effective at decontaminating such surfaces.<sup>86</sup>

# Calicivirus Infections

MARC-ALAIN WIDDOWSON  
STEPHAN S. MONROE

## INTRODUCTION

The illness caused by human caliciviruses was first described in the medical literature in 1929 as “winter vomiting disease.”<sup>1</sup> In 1972, Norwalk virus was identified by immune electron microscopy (IEM) of fecal specimens from an outbreak at a school in Norwalk, Ohio.<sup>2</sup> This marked the first identification of a viral agent as a cause of gastroenteritis, and the event was closely followed by the identification of rotavirus (a reovirus) in 1973 as another viral cause of gastroenteritis.<sup>3</sup> In 1976, human viruses with surface features similar to those of established animal caliciviruses were identified by electron microscopy in stools from young children in the United Kingdom<sup>4</sup> and Sapporo, Japan. With the cloning of the Norwalk virus genome in 1990<sup>5</sup> and with the ensuing development of reverse transcription–polymerase chain reaction (RT-PCR), many related but antigenically diverse viruses were identified and placed into provisionally termed groups called “Norwalk-like viruses” and “Sapporo-like viruses.” These groups subsequently were defined as separate genera in the family *Caliciviridae* and, in 2001, they were given the official genus names of *Norovirus* and *Sapovirus*, respectively.

Human caliciviruses are now acknowledged as one of the most frequent causes of gastroenteritis in both temperate and tropical countries and in persons of all ages. Although illness is often short-lived, symptoms can be debilitating, leading to dehydration and attendant complications, and may be a particular problem in water-stressed or poorly nourished persons who live in the tropics.

## AGENTS

The human caliciviruses, like other members of the family *Caliciviridae*, are small (approximately 27 nm), nonenveloped RNA viruses with a single major capsid protein. The name *calicivirus* refers to the cup-shaped indentations often seen on the surface of particles visualized by electron microscopy. Viruses now classified as sapoviruses often exhibit the typical calicivirus morphology and were frequently called “classic human caliciviruses.” Viruses now classified as noroviruses often lack the distinct surface depressions and were frequently called small, round-structured viruses (SRSV; Fig. 62-1). Individual strains have historically been assigned names based

on the location of the outbreak of gastroenteritis with which they were associated (e.g., Norwalk, Hawaii, Snow Mountain, Southampton, Sapporo).

The RNA genome of Norwalk virus, the prototype norovirus, contains 7654 nucleotides, excluding the poly(A) tail, and is organized into three open reading frames (ORFs).<sup>5,6</sup> The first ORF encodes a nonstructural polyprotein that is processed in infected cells to generate several proteins, including the viral helicase, VPg, protease, and RNA-dependent RNA polymerase. The second ORF encodes the major capsid protein, VP1, and the third encodes a small, basic protein, VP2, that is present in virus particles but whose precise function remains unknown.<sup>7</sup> The genomic organization of sapoviruses is slightly different, with the nonstructural polyprotein and major capsid protein both encoded in ORF1 and the small basic protein encoded in ORF2.<sup>8</sup>

Much has been learned about the structure and antigenicity of noroviruses by studying virus-like particles (VLPs) produced by expression of the capsid protein, using recombinant systems.<sup>9</sup> The precise structure of the VLPs of Norwalk virus has been determined, originally by electron cryomicroscopy<sup>10</sup> and subsequently by x-ray crystallography.<sup>11</sup> These VLPs have also been used as antigens for detecting antibodies and as immunogens for generating specific antisera.<sup>12–16</sup>

Human caliciviruses cannot be grown in cell culture nor passaged in small animals, so it is difficult to characterize the antigenic relationships among virus strains. Cross-challenge studies in humans and IEM findings indicated that there are multiple antigenic types.<sup>17–19</sup> The cloning and sequencing of Norwalk virus<sup>5,6</sup> and several other strains<sup>20,21</sup> in the early 1990s allowed for the classification of human calicivirus strains by genetic analysis. Analyses of the predicted amino acids of the complete capsid protein genes (ORF2) has allowed for classification of noroviruses into five major genetic groups or genogroups (GI–GV), three of which (GI, GII, and GIV) contain viruses detected in humans.<sup>22–25</sup> These genogroups can be further subdivided into more than 29 clusters. Sapoviruses can be similarly classified into five genogroups, four of which contain viruses detected in humans.<sup>26</sup> The precise antigenic relationships among strains within and between genogroups

**FIGURE 62-1** Negative stain electron micrograph of norovirus particles found in the stool of an ill resident during an outbreak of gastroenteritis in a nursing home, August 1999. (Courtesy of Charles Humphrey, Centers for Disease Control and Prevention, Atlanta, GA.)

remain to be established. Noroviruses also have been found in cows, pigs, and mice.<sup>27,28</sup> These strains have not been found in human infections, but recent serologic evidence suggests that zoonotic transmission may occur.<sup>29</sup>

## EPIDEMIOLOGY

The cloning of the norovirus genome in the early 1990s led to the development of sensitive antigen and antibody detection assays that did not require human reagents. These assays have allowed for better understanding of the epidemiology of noroviruses through more complete outbreak investigations, community-based incidence studies, and cross-sectional serosurveys throughout the world.

Norovirus disease often presents as large outbreaks of acute gastroenteritis of short duration in persons of all ages in a variety of settings. Investigations of these outbreaks have been conducted almost exclusively in more developed countries but have proved valuable in elucidating mechanisms of virus transmission (Table 62-1). Noroviruses are highly infectious and are transmitted primarily through the fecal-oral route either by consumption of contaminated food or water or by direct person-to-person spread. Moreover, aerosolization of vomitus droplets has been documented as a mode of transmission<sup>30</sup> and evidence now strongly suggests an important role for environmental contamination and fomites as a source of continuing infection.<sup>31,32</sup>

Attack rates in outbreaks can be over 50%, and there is often substantial secondary spread to contacts of cases. Outbreaks occur year-round, but are particularly common and protracted in the colder months in closed (e.g., nursing homes) or semi-closed (e.g., hotels) settings where transmission is predominantly from person to person. From July 1997 to June 2000, 39% of 264 norovirus outbreaks confirmed by the Centers for Disease Control and Prevention were associated with restaurants or catered events, 25% with nursing homes and hospitals, 13% with schools and day-care centers, 10% with vacation settings (e.g., cruise ships), and 12% with other settings.<sup>33</sup> Outbreaks of norovirus gastroenteritis have been recently reported as a particular problem on cruise ships.<sup>23</sup> Sapoviruses have rarely been reported to cause outbreaks.

Foodborne outbreaks of norovirus are often associated with salads, sandwiches, bakery products, and other foods that are handled and contaminated just before serving by infected foodhandlers. Contaminated oysters have been frequently associated with widespread outbreaks of norovirus gastroenteritis.<sup>34</sup> Contamination of fresh produce at the source also has been documented<sup>35</sup> and may be an under-recognized cause of norovirus infection. Waterborne outbreaks of norovirus gastroenteritis in developed countries have been associated with recreational water<sup>36</sup> and with sewage contamination of drinking water. Both groundwater well sources<sup>37</sup> and municipal water systems have been implicated,<sup>38</sup> the latter usually with an accompanying chlorination failure. The waterborne route of infection may be more important in tropical countries where poor water quality is a problem.

Recently conducted prospective population- or physician-based studies have used RT-PCR to better characterize the epidemiology of endemic norovirus illness in adults and children. A Dutch study found norovirus in 16% of persons of all ages with gastroenteritis,<sup>39</sup> and a recent Australian study, also population-based, reported a comparable estimate of 11%,<sup>40</sup> suggesting that noroviruses are the most common cause of acute gastroenteritis of adults.

Studies in both developed and developing settings have also led to an increasing appreciation that noroviruses are an important cause of acute gastroenteritis among young children, though they remain second to rotaviruses. In Finland, a prospective study of children under two years of age detected rotavirus in 29% of 832 episodes of gastroenteritis, noroviruses in 20%, and sapoviruses in 9%.<sup>41</sup> Rotavirus gastroenteritis was on average more severe than that of norovirus, while sapovirus infection was associated with still milder symptoms. Similarly, a study of children under five years of age hospitalized with nonbacterial gastroenteritis in urban Indonesia found rotavirus in stools of 47% of cases and norovirus in 24%.<sup>42</sup>

Molecular analysis of norovirus detected in outbreaks and sporadic cases suggests that infections with GII strains are several-fold more common than those of GI strains. Certain GII strains have become predominant for a brief time, both globally and nationally,<sup>43</sup> although specific biologic properties that led to this predominance have not yet been defined.

**Table 62-1** Characteristics of Noroviruses That Facilitate Spread

Characteristic	Observation	Consequences
Low infectious dose	Less than 100 particles	Permits multiple modes of spread; person to person, via airborne droplets of vomitus, food, water, and environmental contamination
Prolonged asymptomatic shedding	Up to 2 weeks	Increased secondary spread and poses difficulties in implementing control measures
Environmental stability	Resists chlorine, heating, freezing, and desiccation	A contaminated environment can act as a source of infection for several weeks
Substantial strain diversity	Multiple genetic and antigenic types	Require composite diagnostics; repeat infections by different strains
Lack of lasting immunity	Disease can recur with reinfection by same strain	Childhood infection does not protect from disease in adulthood; difficult to develop vaccine with long-lasting immunity

Modified from Parashan U, Quiroz ES, Mountas AW, et al: "Norwalk-like viruses." Public health consequences and outbreak management. *MMWR Recomm Rep* 50:1-17, 2001.

Nonetheless, seroprevalence studies using recombinant antigens of viruses from GI (Norwalk virus) and GII (Mexico virus) demonstrate that infections with both groups of viruses are extremely common throughout the world, including among isolated groups of Amazonian Indians.<sup>44</sup> A study of over 2000 sera from persons in 11 different sites in 4 countries in southern Africa found an overall seroprevalence of antibodies to both Norwalk virus and Mexico virus of greater than 90%, even in children of 5 years of age.<sup>45</sup> However, there is some suggestion that in developed countries, antibodies to GI strains may be acquired later in childhood and remain at a slightly lower seroprevalence in adults than antibodies to GII strains.<sup>46,47</sup> Low socioeconomic status has been associated with increased seroprevalence of norovirus antibodies in Canada and Chile.<sup>48,49</sup> Studies in northeast Brazil have documented 0.7 seroconversions per child per year, maximum in the second year of life, with 8 different genotypes (5 in group I; 3 in group II) among 12 children.<sup>50,51</sup>

The few studies that have looked at norovirus infections among HIV-infected persons in developed and developing countries have not found evidence to support a major pathogenic role for caliciviruses in this population, although increased viral shedding has been weakly associated with immunodeficiency.<sup>52,53</sup>

## DISEASE

The incubation period for norovirus-associated gastroenteritis in humans is usually between 24 and 48 hours (median in outbreaks is 33 to 36 hours), but illness can occur within 12 hours of exposure.

Norovirus gastroenteritis usually presents as acute-onset vomiting, watery nonbloody diarrhea, with accompanying symptoms of abdominal cramps, nausea, headache, malaise, and, in some cases, a low-grade fever. Symptoms last 24 to 60 hours but can be quite severe, with as many as 20 vomiting episodes in a 24-hour period reported. A high proportion of cases with vomiting (over 50%) is one of the characteristics that help differentiate outbreaks of norovirus from those of bacterial etiology. Dehydration and ensuing problems are the most common complications of infection, especially among the very young and elderly, and may require medical attention or hospitalization. Fatalities are rare. Recovery is usually complete with no evidence of any serious long-term sequelae. Norovirus disease among young children is usually less severe than rotavirus disease, although the number of daily episodes of vomiting may be similar.<sup>54</sup>

Studies with volunteers given stool filtrates from norovirus-infected persons have shown that as many as 30% of infections may be asymptomatic, and a Dutch study found 5% of well controls with evidence of norovirus in stool by RT-PCR.<sup>39</sup>

## PATHOGENESIS AND IMMUNOLOGY

As few as 10 to 100 ingested norovirus particles are thought to be sufficient to initiate infection in humans, and shedding of virus in the stool generally begins along with onset of symptoms.

Use of molecular detection methods in volunteers fed stool filtrates has indicated that virus antigens can be found in stools for up to two weeks after recovery.<sup>55</sup> Examination by

light microscopy of biopsies of the proximal small intestine of norovirus-infected volunteers has shown blunting and broadening of the intestinal villi, vacuolation of the villus epithelial cells, mononuclear cell infiltration into the lamina propria, but an intact mucosa.<sup>56</sup> Histological lesions have not been found in biopsies of the colonic and gastric mucosa.<sup>57</sup> This suggests that replication of virus is limited to the small intestine; however, since no biopsies from areas of small bowel other than the jejunum have been examined, the extent of small-intestinal involvement and sites of viral replication remain unknown. Diarrhea is thought to be caused by several mechanisms, including reduced absorptive capacity of the disrupted epithelium, proliferation of the secretory crypt cells, and reduced expression of certain digestive enzymes, such as sucrase, which leads to an increased osmotic pull of accumulated carbohydrates in the gut lumen. Nausea and vomiting are probably induced by disrupted gastric motor function and a pronounced delay in the emptying of gastric contents into the small intestine.<sup>58</sup>

Mechanisms of immunity to norovirus infection remain unclear. Volunteer studies originally showed that some subjects developed a short-lived immunity of 6 to 14 weeks, which correlated with a rise in serum antibody levels. Yet these same individuals were susceptible to illness again when rechallenged with the same strain over three years later.<sup>59</sup> Immunity appears to be strain specific, and given the genetic variability in circulating noroviruses, individuals are likely to be repeatedly infected with noroviruses during their lifetime. Interestingly, in challenge studies, individuals with high levels of pre-existing serum antibody paradoxically seemed predisposed to illness, while a proportion of individuals remained asymptomatic with low antibody titers despite repeated challenge.<sup>55,60</sup> Multiple exposures to the same strain may eventually induce improved immunity,<sup>60</sup> an observation that gives hope to the development of a future vaccine. Host genetic factors are now recognized as important determinants of susceptibility to infection and may explain many of the apparent paradoxes from earlier studies. Human ABH histo-blood group antigens are expressed on the surface of gut epithelial cells and are thought to act as receptor sites for noroviruses. One of the first studies of the role of these antigens found that volunteers of blood group O were more susceptible to infection with Norwalk virus and more likely to be symptomatic once infected than were persons with blood group B.<sup>61</sup> Investigations of the binding of different norovirus strains with different carbohydrate moieties have found that particular antigens—H type 1 and Lewis<sup>b</sup>—bind strongly to Norwalk virus VLPs. Individuals who are secretors (Se<sup>+</sup>) express *FUT2* fucosyltransferase that makes H type 1 and Lewis<sup>b</sup> antigens, and therefore these persons are more susceptible to infection with Norwalk virus than are nonsecretors (Se<sup>-</sup>).<sup>62</sup> Different norovirus strains may have specific binding properties to different blood group antigens.<sup>63</sup> Since ABH histo-blood group antigen expression varies among different populations around the world, it is possible that the distribution of circulating norovirus strains may vary in different parts of the world.

## DIAGNOSIS

Norwalk virus was initially identified by IEM,<sup>2</sup> and although electron microscopy is still occasionally used today, it is

generally too cumbersome for routine use. Direct detection of viral antigen in stools was historically done using reagents derived from human volunteers.<sup>64</sup> These assays suffered from low sensitivity and high levels of background reactivity. More recently, antigen detection assays based on reagents derived from recombinant-expressed capsid proteins have been shown to be sensitive and specific for detecting a variety of norovirus strains.<sup>65,66</sup>

The current state-of-the-art tool for diagnosing noroviruses and sapoviruses, using stool samples, is RT-PCR. Since the original description of an RT-PCR assay for detecting Norwalk virus,<sup>67</sup> dozens of assays have been described that use primers targeted to conserved regions of the RNA-dependent RNA polymerase gene,<sup>67–70</sup> with direct comparisons indicating that no single assay is best for detecting all known strains.<sup>71</sup> More recently, assays using primers targeted to the capsid protein gene have been used to detect and type norovirus strains.<sup>24,72</sup> The latest advance in detection of noroviruses is the use of real-time RT-PCR assays, which employ fluorogenic probes or dyes.<sup>73–76</sup> These highly sensitive assays offer great promise for improved detection of virus in stool samples collected after the resolution of symptoms, when the level of viral shedding is low.

Serologic diagnosis of norovirus infection was initially performed by using IEM or assays utilizing reagents from human volunteers.<sup>77–80</sup> The availability of recombinant-expressed norovirus capsid proteins has allowed for the development of highly sensitive and specific assays for detecting historic exposure (seroprevalence) and recent exposure (seroconversion) to noroviruses.<sup>72,81–84</sup> The frequent occurrence of cross-reactive antibody responses in infected individuals limits the usefulness of these assays for determining the subtype of the infecting strain.

## TREATMENT AND PROGNOSIS

Calicivirus gastroenteritis is self-limiting, and patients usually make a rapid and full recovery. No specific antiviral treatment exists. Rehydration therapy and treatment to correct electrolyte disturbances may be necessary, usually via oral administration, but in some cases administration of intravenous fluids is required. In some cases of severe vomiting, antiemetic drugs may be of use. In experimentally infected adults, oral administration of bismuth subsalicylate reduced the severity of abdominal cramps and the duration of gastrointestinal symptoms<sup>85</sup>; however, the American Association of Pediatrics does not recommend the use of such pharmacologic agents in children.<sup>86</sup>

## PREVENTION AND CONTROL

Standard hygienic precautions, including frequent hand washing and care in the disposal or cleaning of materials soiled with feces or vomitus, will help prevent calicivirus infection. Due to the lack of a cell-culture system for human caliciviruses, studies to determine the efficacy of disinfectants to inactivate noroviruses have not been performed. However, prompt use of chlorine solutions at a concentration of 1000 parts per million on hard surfaces is recommended in the United Kingdom to help control outbreaks in hospitals.<sup>87</sup>

Correct handling of ready-to-eat foods and exclusion from work of ill foodhandlers until at least 24 hours after resolution

of symptoms (encouraged by provision of paid sick leave) will likely reduce foodborne transmission of noroviruses. Although viral antigens have been detected in stools 13 days after virus challenge in volunteers,<sup>88</sup> the public health significance of prolonged shedding remains unclear. Noroviruses may be able to survive chlorine levels in excess of those routinely present in public water systems.<sup>89</sup> Water treatment processes aimed at providing safe water in poorer countries may not be fully effective against caliciviruses.

The antigenic diversity of norovirus strains and the apparent lack of long-term immunity have challenged the development of a vaccine. Nonetheless, early development of norovirus vaccines has begun with use of recombinantly expressed VLPs. These VLPs have proved immunogenic in humans<sup>90</sup> and have been administered orally using transgenic potatoes,<sup>91</sup> raising the interesting possibility of an edible vaccine.

## Astroviruses, Enteric Adenoviruses, and Other Gastroenteritis Viruses

JOSEPH S. BRESEE  
ROGER I. GLASS

### INTRODUCTION

Diarrheal disease remains one of the most common causes of morbidity and mortality in developing countries. The problem is particularly acute among young children, who will have an estimated 15 episodes of diarrhea in the first five years of life<sup>1</sup> and among whom 2.5 million deaths will occur each year.<sup>2</sup> For up to half of all episodes, an etiologic agent cannot be found. The importance of viral agents as causes of diarrheal disease has been increasingly appreciated, beginning with the discovery of rotavirus<sup>3</sup> and caliciviruses<sup>4</sup> in the 1970s. More recently, advances in detection methods for some other viruses, such as astroviruses and enteric adenoviruses, have led us to appreciate their role as causes of diarrheal disease. In addition, a variety of other viruses, such as picobirnaviruses, coronaviruses, and toroviruses, have been associated with gastroenteritis, but their clinical and public health importance remains unclear (Table 63-1). Many of these viruses may be responsible for the fraction of illness for which a pathogen cannot be found and a better understanding of their epidemiology will have implications for programs to decrease morbidity and mortality in developing countries.

### ■ Astroviruses

#### AGENTS

Astroviruses were first identified in 1975<sup>5,6</sup> and named based on a characteristic 5- or 6-pointed appearance noted by electron microscopy (EM). Since 1990, improvements in diagnostic methods, including the adaptation of astrovirus to grow in continuous cell lines<sup>7</sup>; sequencing and elucidation of the structure of the genome<sup>8-10</sup>; and development of improved methods of detection, including enzyme immunoassays and reverse-transcription polymerase chain reaction,<sup>11-14</sup> have led to new insights into the role of astrovirus in human disease. It is now clear that astroviruses are a common cause of sporadic gastroenteritis among children, possibly second only to

rotavirus, and may be associated with large-scale outbreaks of diarrhea as well.

Astroviruses are 28- to 30-nm, spherical, nonenveloped viruses with a positive sense ssRNA genome and have been classified in their own family, Astroviridae.<sup>15</sup> Eight serotypes of human astroviruses have been identified.<sup>16,17</sup> Of these, type 1 is predominant in most studies, accounting for more than half of strains isolated<sup>16,18,19</sup>; types 2, 3, and 4 each account for 10% to 16% of astrovirus detections; and types 5, 6, 7, and 8 are less uncommonly detected.<sup>16,17</sup> The relative distribution of types seems to vary by geographic location and by year,<sup>20</sup> and more variability may be found in developing countries.<sup>21,22</sup>

#### EPIDEMIOLOGY

Gastroenteritis associated with astroviruses has been reported worldwide, both as sporadic disease and as outbreaks. Cases of astrovirus-associated gastroenteritis are most common among children less than 2 years of age,<sup>19,23-32</sup> and are less frequent among older children and adults.<sup>33,34</sup> In volunteer studies, most adults neither became infected nor developed diarrhea.<sup>33,35</sup> However, in a large outbreak among schoolchildren,<sup>36,37</sup> teachers became ill as well, perhaps as a result of a large dose of virus in this type of setting or a different mechanism of spread. In addition, outbreaks have been reported among the elderly, probably due to waning immunity with increasing age.<sup>38-40</sup>

Gastroenteritis associated with astrovirus, like rotavirus, occurs in both developed<sup>19,23,24,27-30,41-43</sup> and developing countries,<sup>32,44-48</sup> suggesting that improvements in water and sanitation are unlikely to decrease disease incidence. In temperate climates, astrovirus diarrhea cases peak in winter,<sup>17,19,24,29,31</sup> whereas the seasonality is less clear in tropical settings.<sup>32,44,46</sup> With improvements in detection methods, astrovirus represents an important cause of community-acquired and nosocomial illness and may be the most common viral cause of gastroenteritis in children after rotavirus and possibly Norwalk-like viruses.<sup>19</sup> In developing countries, astroviruses have generally been detected in less than 10% of young children treated for gastroenteritis in outpatient clinics or in hospitals, and the lower proportions reported from some studies (<1%–3%) may reflect insensitive detection methods rather than true prevalence.<sup>19,21,42,45,47-50</sup> Even so, one study in rural Mexico has found astrovirus to be the most common cause of diarrhea in the first three years of life, causing 26% of diarrheal episodes in a prospectively followed cohort.<sup>32</sup> Outbreaks of astrovirus gastroenteritis have been reported in schools,<sup>36,37</sup> day-care centers,<sup>25,51,52</sup> hospitals,<sup>26,29,39,53,54</sup> nursing homes,<sup>38,40</sup> and households.<sup>32,55</sup> Nosocomial spread of astroviruses may be common.<sup>56</sup> While the modes of transmission are still unknown, the primary mode of spread of virus is likely to be through fecal–oral contamination via person-to-person contact,<sup>33,35,36,53</sup> although the stability of the virus in water may indicate that waterborne spread is possible.<sup>57</sup>

#### DISEASE

Astroviruses cause a syndrome characterized by 2 to 5 days of watery diarrhea, often accompanied by vomiting and less often by high fever, abdominal pain, and other constitutional symptoms.<sup>23,29,44,46</sup> It is generally milder than rotavirus, less commonly resulting in dehydration,<sup>19,23,26,39,44</sup> and rarely

**Table 63-1** Summary of Virologic and Epidemiologic Features of Certain Viruses Associated with Gastroenteritis

Virus	Family	Taxonomy	Detection	Epidemiology	Comment
Astrovirus	Astroviridae	28–30nm, ssRNA, N-env; 10% have 5–6 point star appearance; 8 serotypes	EM, IEM, EIA, RT-PCR	Endemic, most disease in children <2 years; epidemic, children and adults, including elderly; daycare, schools, hospitals	No clear seasonality in tropical countries; fairly common cause of viral diarrhea in children; less severe than rotavirus
Enteric adenovirus	Adenoviridae	70–80nm, dsRNA, icosahedral, N-env; 2 main serotypes	EIA, EM, IEM, RT-PCR, culture, DNA probes, hybridization	Endemic disease in children <2 years;	No clear seasonality; disease as severe as rotavirus, but less common
Picobirnavirus	Birnaviridae	35nm, dsRNA, bisegmented genome	EM, PAGE, RT-PCR	Associated with diarrhea in HIV infected adults; no clear association with diarrhea in healthy persons	Possible association with <i>Cryptosporidium</i> infection.
Coronavirus	Coronaviridae	60–200nm, ssRNA, pleomorphic, env, with club-shaped projections give a halo appearance	EM	Not known	May cause diarrhea in children and adults; possible association with tropical sprue and NEC
Torovirus	Coronaviridae	100–150nm, ssRNA pleomorphic, env, with club-shaped projections	EM	Not known	Possible cause of diarrhea in humans

EIA, enzyme immunoassay; EM, electron microscopy; env, enveloped; IEM, immune electron microscopy; N-env, nonenveloped; RT-PCR, reverse transcriptase–polymerase chain reaction.

associated with death.<sup>45</sup> Lactose intolerance<sup>43,58</sup> and poor weight gain<sup>46</sup> have been reported following astrovirus infection, and children with poor nutritional status may develop more severe disease<sup>46</sup> or chronic diarrhea.<sup>50</sup> Illness among adults is generally mild and of short duration.<sup>33,35,39</sup> However, in studies of immunocompromised persons, astrovirus is often the most common virus detected in persons with diarrhea and associated with prolonged shedding of virus.<sup>59–61</sup> HIV infection was associated with more severe astrovirus disease in children with HIV in Malawi.<sup>21</sup> Indirect evidence suggests that immunity to astrovirus develops early in life.<sup>25,33,35</sup>

Astrovirus infects intestinal epithelial cells. The incubation period is 3 to 4 days,<sup>33,35</sup> but may be shorter in outbreak settings.<sup>37</sup> Children may shed virus 1 to 2 days prior to illness and for 4 to 5 days following illness,<sup>25,29,51</sup> but shedding for 3 weeks has been reported when more sensitive detection methods have been used. Since most illness with astroviruses is found in young children and elderly persons, it is assumed that protection from illness is conferred by infection, and that the protection is relatively durable. Like many other enteric viruses, the immunologic correlates of protection are poorly understood for astroviruses.

## DIAGNOSIS

Until recently, electron microscopy was the only method to detect astrovirus in fecal specimens, but was relatively insensitive.<sup>9,24,26,31,36,37,40,47,53,58,62,63</sup> Enzyme immunoassays have been developed,<sup>11,42</sup> which were more sensitive, easier, and less expensive to use.<sup>23,25,30,36,42,44,46,64</sup> Molecular diagnostic methods including reverse transcriptase–polymerase chain reaction and probes, as well as virus cultivation, are available in research laboratories.<sup>65</sup>

## TREATMENT, PROGNOSIS, AND PREVENTION

Therapy for astrovirus diarrhea includes rehydration with oral or intravenous fluids. Illness is generally mild and self-limited, but malabsorption and lactose intolerance have been reported following infection. Death associated with astroviruses is rare.<sup>43,45,58</sup>

In outbreaks, identification of the source of infection, such as food or contact with ill persons, may be helpful in preventing further illness. Sporadic cases are common in children and no methods of prevention have been identified. Since the

infection may be spread through close personal contact, enteric precautions including appropriate hand-washing practices and isolation of ill persons may be advisable.

## ■ Enteric Adenovirus

### AGENTS

When adenoviruses were first identified in fecal specimens of children with diarrhea, their etiologic role was questioned because adenoviruses are common causes of other illnesses (e.g., URIs) in children and are excreted in the stool. But unlike the common respiratory adenoviruses, enteric adenoviruses were difficult to grow and were therefore distinguished as the fastidious enteric adenoviruses (FEAs). Eventually, these FEAs were placed in their own group and found to belong to two predominant serotypes, 40 and 41. Besides these serotypes, only serotype 31 has occasionally been causally associated with gastroenteritis. Like astroviruses, the development of rapid, sensitive diagnostic assays for the detection of EAs has increased our appreciation of their role as causes of diarrhea in children.

Adenoviruses are members of the family Adenoviridae and of the genus *Mastadenovirus*. The 47 defined serotypes are divided into 6 subgroups (A–F); serotypes 40 and 41 are the only members of subgroup F (called enteric adenoviruses because they have been associated with gastroenteritis in humans).<sup>66,67</sup> Enteric adenoviruses are nonenveloped, icosahedral, double-stranded DNA viruses, and are 70 to 80 nm in size.

### EPIDEMIOLOGY

Like rotavirus and astrovirus diarrhea, diarrhea associated with enteric adenoviruses occurs primarily among children less than 2 years of age. Infection is probably universal, and the age-specific incidence does not appear to differ between temperate and tropical countries, suggesting that improvements in water and sanitation will not decrease the incidence of disease.

Compared to other viral agents in developing countries, EAs appear to account for a smaller proportion of diarrheal disease than in developed countries. Enteric adenoviruses generally have been detected in 1% to 4% of children with diarrhea in many studies,<sup>19,49</sup> although they have been detected commonly in some studies. Enteric adenoviruses were more common than rotavirus in a rural outpatient setting in Guatemala (14% of children with diarrhea had EA detected in stool compared to 5% with rotavirus), and were associated with 31% of hospital admissions for diarrhea.<sup>68</sup> In two South African studies, 6.5% to 13.2% of hospital admissions for diarrhea were associated with EAs<sup>69,70</sup>; in one study,<sup>70</sup> EAs were detected as often as rotaviruses. In the few studies that have examined the role of EAs in an adult population, they appear to be less important causes of gastroenteritis than in children. No seasonality of EA infections was apparent in studies in temperate<sup>31,71–73</sup> or tropical countries,<sup>68,74</sup> but few studies have reviewed multiple seasons.

### DISEASE

Infections with EA can range from being mild or asymptomatic to producing profuse, nonbloody, watery diarrhea

and vomiting.<sup>71,72,75–79</sup> Children often have 6 to 10 stools per day, and the mean duration of illness is 5 to 9 days.<sup>68,71,72,75–78</sup> Abdominal pain<sup>71,76</sup> and 2 to 3 days of low-grade fever (<38.5°C) are also frequently present, whereas temperatures greater than or equal to 39°C occur in less than 10% to 25% of children.<sup>71,75</sup> Mild isotonic dehydration may occur in 15% to 50% of children,<sup>71,72,76</sup> and only severe cases require hospitalization. Respiratory symptoms, including pneumonia, have been associated with EA infections but are present less commonly than with other adenoviruses.<sup>72,75,77</sup> Asymptomatic infections have been documented in 8% and 17% of children in day-care center studies.<sup>23,68,71,72</sup> Serum electrolytes are usually normal, and a slight leukocytosis may be present in a minority of children.<sup>71</sup>

Gastroenteritis associated with EAs has a similar presentation among patients in developed and developing countries. However, enteric adenoviruses may be associated with chronic diarrhea and less common serotypes in HIV-infected subjects.<sup>59,80–84</sup> Deaths from EA gastroenteritis are uncommon, but have been reported, particularly among immunocompromised children.<sup>75,85,86</sup> Long-term complications appear to be rare, but lactose intolerance<sup>71</sup> and malabsorption<sup>87</sup> have been reported and may exacerbate disease among children in developing countries where malnutrition is prevalent.

Differentiation of EA-associated gastroenteritis from other causes of viral gastroenteritis is difficult. EA-associated diarrhea may be more severe and prolonged than viral gastroenteritis caused by other agents<sup>71,72,88</sup> and is commonly associated with a high fever and dehydration similar to rotavirus.<sup>71,88</sup>

Like other viral agents of gastroenteritis, the exact mode of transmission is unknown. EAs are probably transmitted by fecal–oral spread, by person-to-person contact, or by respiratory droplets. No foodborne or waterborne outbreaks have been described.<sup>89</sup>

The incubation period of the disease is 7 to 10 days,<sup>77,78,90</sup> and viral shedding may persist for 10 to 14 days.<sup>90</sup> Mechanisms of diarrhea and immunity associated with EA are poorly understood. Type 40- and 41-specific antibodies develop following infection<sup>71,91,92</sup> and can be detected in the absence of recent diarrheal illness.<sup>69,92</sup> Children can become ill when reinfecting with EA.<sup>93</sup> However, illness among adults is uncommon, even in outbreak settings where they have a high likelihood of exposure.

### DIAGNOSIS

Electron microscopy (EM) was first used to detect enteric adenoviruses in fecal specimens when they are shed in large amounts (as many as 10<sup>11</sup> particles/gram of feces). Since EM cannot distinguish EAs from nonenteric serotypes,<sup>94</sup> immune electron microscopy (IEM) can enhance sensitivity and specificity of EA detection.<sup>95–98</sup> Enzyme immunoassays using monoclonal antibodies to types 40 and 41 and to the adenovirus hexon common to all serotypes have been developed.<sup>98–102</sup> These are the easiest, most rapid methods for detection<sup>103</sup> and have proven to be highly sensitive and specific compared to IEM.<sup>98</sup> There are currently no commercial kits using DNA detection methods. Enteric adenoviruses grow in Graham 293 cells, a cell line transformed by adenovirus type 5.<sup>104</sup> Viruses can then

be identified using one of the preceding methods or by use of restriction enzyme analysis.

## TREATMENT, PROGNOSIS, AND PREVENTION

No specific therapy is available for EA gastroenteritis, so treatment is directed toward prevention and treatment of dehydration. Oral rehydration solutions are effective in treating diarrhea with mild and moderate dehydration, and severe dehydration may require use of intravenous fluids.

Prevention of illness is currently not possible due to lack of understanding of risk factors for transmission. Attention to good hand washing when caring for ill persons seems reasonable.

## ■ Novel Viruses Associated with Gastroenteritis

### PICOBIRNAVIRUS

First identified in 1985,<sup>105</sup> picobirnaviruses (PBVs) have since been detected in a variety of animals.<sup>106–111</sup> The virus has since been detected in human fecal specimens from patients with and without diarrhea,<sup>59,112–115</sup> but has been associated with disease only in a study of HIV-infected adults in the United States<sup>59</sup> and Argentina.<sup>116</sup>

Picobirnaviruses are small (pico), bisegmented (bi-RNA) viruses that are members of the family Birnaviridae. Atypical picobirnaviruses have been detected with three segments of RNA.<sup>112</sup> On electron microscopy, the virus is a 35-nm, discrete virus with no distinctive surface structure.

Little is known about the distribution or incidence of picobirnaviruses. In two studies, PBVs have been detected from diarrheic stools of adults with coexistent *Cryptosporidium* infection, and in one study, HIV-infected patients with chronic diarrhea excreted the virus for seven months.<sup>59,113</sup> The geographic or temporal distribution of picobirnaviruses is unknown, although viruses have been isolated from humans in several countries.

No serologic immune response, measured by IEM, was detected in a group of adults with HIV,<sup>59</sup> although serum antibody has been detected by solid-phase IEM in infected rabbits.<sup>110</sup>

Although PBVs may be seen by EM, the most sensitive and specific methods of detection involves identification of two segments of RNA by polyacrylamide electrophoresis from a stool specimen.<sup>59</sup>

### CORONAVIRUSES

Coronaviruses were first reported in association with diarrhea in adults<sup>117</sup> and tropical sprue among children and adults in India in 1975.<sup>118</sup> While subsequent reports documented detection of coronavirus-like particles (CVLPs) in stools of persons with diarrhea, they could not associate CVLPs with diarrhea.<sup>119,120</sup>

Coronaviruses are pleomorphic, 60 to 200 nm, ssRNA viruses that belong to the family Coronaviridae. Because of their pleomorphic appearance, misdiagnosis is problematic and no confirmatory test is available. Consequently, the prevalence of human enteric coronaviruses (HECVs) is unknown,

and while they have been detected in studies in several countries,<sup>16,24,45,62,121–129</sup> they are not clearly associated with disease. In studies that have compared rates of HECV detection in stools from patients with diarrhea versus controls, the results are mixed. Because of the long duration of shedding and the possibility for asymptomatic infection, the pathogenicity of HECVs may be difficult to prove by comparing rates of detection between well and ill persons. Many studies have reported the majority of viral detections among young children and infants,<sup>24,121,126–128,130</sup> but detections among adults are common.<sup>24,84,119,127,131</sup> With some exceptions,<sup>45,126,130</sup> most studies have reported no differences in detection by time of year.<sup>127</sup> Mode of spread of HECVs is unknown.
